Preface

This volume is the proceedings of ALIFE 14: The Fourteenth International Conference on the Synthesis and Simulation of Living Systems, held July 30th to August 2nd, 2014, in Manhattan, New York (http://alife14.org/, or http://alife2014.alife.org/). ALIFE is the largest conference series focusing on the study of Artificial Life. Since its inception led by Chris Langton in 1987, it has been held at various international locations every other year, alternating with ECAL (European Conference on Artificial Life) since 1991. The history of those conferences and past websites can be found on the website of the International Society for Artificial Life (ISAL, http://alife.org/).

ALIFE 14 attracted a total of 203 submissions. Following the past ALIFE and ECAL rules, we solicited submissions in two formats: full paper (up to 8 pages) and extended abstract (2 pages). The extended abstract format was implemented in 2008 (ALIFE 11) to promote participation of researchers working in disciplines where conference submissions require abstracts only. This format may be used for presenting either original work or recently published work. Both full papers and extended abstracts were peer-reviewed by multiple (typically three to four) Program Committee members. As a result, we accepted 102 submissions for oral presentations and 62 submissions for poster presentations (oral acceptance rate: 50.2%).

The program of ALIFE 14 is composed of a number of scientific/professional/creative activities, including:

- Five keynote talks given by the following internationally renowned speakers:
 - Naomi Leonard (Princeton University, USA)
 - Jesse Louis-Rosenberg (Nervous System, USA)
 - Karl Sims (Digital Media Artist, USA)
 - Leroy (Lee) Cronin (University of Glasgow, UK)
 - John H. Conway (Princeton University, USA)
- Twenty parallel sessions on the following topics:
 - Evolutionary dynamics (3 sessions)
 - Robot and agent behavior (3 sessions)
 - Boolean networks, neural networks and machine learning (2 sessions)
 - Artificial chemistries, cellular automata and self-organizing systems (2 sessions)
 - Collective behaviors (2 sessions)
 - Social dynamics and evolution (2 sessions)
 - In-vitro and in-vivo systems
 - Artificial evolutionary ecosystems
 - Soft robotics and morphologies
 - Collective robotics
 - Evolutionary art, philosophy and entertainment
 - Methodologies
- A poster session with a plenary "Poster Blitz Movie Show"

• Nine workshops:

- Computing with Biomolecules: From Network Motifs to Complex and Adaptive Systems (Organizers: Christof Teuscher, Darko Stefanovic, Milan N. Stojanovic)
- CoSMoS 2014: 7th Workshop on Complex Systems Modelling and Simulation (Organizers: Susan Stepney, Paul Andrews)
- Exploiting Synergies Between Biology and Artificial Life Technologies: Tools, Possibilities, and Examples (Organizers: Kasper Stoy, Martin Hanczyc, Ioannis Ieropoulous, Michal Wagner, Leroy Cronin)
- Human-Machine Affective Coordination (Organizers: Luisa Damiano, Paul Dumouchel, Hagen Lehmann)
- Information Theoretic Incentives for Artificial Life (Organizers: Christoph Salge, Keyan Ghazi-Zahedi, Georg Martius, Daniel Polani)
- MEW 2014: Fourth Morphogenetic Engineering Workshop (Organizers: René Doursat, Hiroki Sayama)
- SB-AI 2014: What Can Synthetic Biology Offer to (Embodied) Artificial Intelligence?
 (Organizers: Luisa Damiano, Yutetsu Kuruma, Pasquale Stano)
- WebAL1: Artificial Life and the Web
 (Organizers: Tim Taylor, Josh Auerbach, Josh Bongard, Jeff Clune, Simon Hickinbotham, Greg Hornby)
- Third Workshop on the Evolution of Physical Systems (Organizers: John Rieffel, Jean-Baptiste Mouret, Nicolas Bredeche, Evert Haasdijk)

• Six tutorials:

- Algorithmic Graph Chemistry in Action (Instructors: Jakob L. Andersen, Christoph Flamm, Daniel Merkle)
- An Introduction to Statistical Analysis of Alife Experiments (Instructor: Mark Wineberg)
- Creating High-Quality Plots with Python and Matplotlib (Instructor: Jean-Baptiste Mouret)
- Evolutionary Robotics
 (Instructors: Nicolas Bredeche, Stéphane Doncieux, Jean-Baptiste Mouret)
- Evolving Neural Networks (Instructor: Risto Miikkulainen)
- In Silico Experimental Evolution with the Aevol Software (Instructors: Guillaume Beslon, Carole Knibbe, David P. Parsons, Dusan Misevic)
- The first ISAL summer school:
 - Historical and Philosophical Perspectives on Artificial Life (instructor: Mark Bedau)
 - Unconventional Computing (instructor: Susan Stepney)
 - Digital Evolution (instructor: Charles Ofria)
 - Evolutionary Developmental Robotics (instructor: Josh Bongard)
- A science visualization competition
- A career advising luncheon for postdocs and graduate students
 - ... and other social events

Needless to say, organizing a conference requires a lot of work, and we would not have been able to achieve our goal without help from a number of individuals and organizations. First and foremost, our highest gratitude goes to Craig Ryan, our event coordinator, for his heroic work in essentially all aspects of the conference, including negotiations with the conference venue, handling registrations, and making millions of other logistic arrangements. We are also very fortunate to have had Emily

Ryan design the impressive "ALIFE 14 bird" artwork used on the conference website and the cover of this proceedings volume, which has become a unique, memorable visual identity to the conference. We also thank Ira Fraitag and Mike Blain for their help.

To maintain a high standard of scientific quality for the conference, it is critical to have a rigorous peer review process to evaluate submissions. Luckily, we were able to rely on a very cooperative, hard working Program Committee and other reviewers who have provided constructive comments on the submissions in a timely manner (individual names listed below in an alphabetical order).

We are very grateful to the following sponsors for their financial and in-kind support for the conference, which was essential in making ALIFE 14 a successful event:

- US National Science Foundation
- MIT Press
- Cornell University
- Thomas J. Watson School of Engineering and Applied Science at Binghamton University
- Wolfram Research

Finally, we would like to express our sincere thanks to keynote speakers and contributing authors whose quality presentations are what make ALIFE 14 a truly unique, outstanding academic meeting.

We hope you will enjoy the breadth and depth of various topics covered in this volume. They collectively represent the state of the art of Artificial Life, a vibrant intellectual melting pot stirred and served fresh in the middle of Manhattan.

Part I Keynotes

Hybrid Chemo-Robotic Systems for Embodied Chemical Evolution

Leroy Cronin¹

¹Complex Chemical Systems Lab, School of Chemistry, University of Glasgow, Glasgow, G12 8QQ, UK.

Lee.cronin@Glasgow.ac.uk

Abstract

The development of inorganic systems capable of evolution as a fundamentally less complex 'emergent' model of prebiotic evolution is proposed as a solution to the information paradox that could pre date other more complex systems e.g. heteropolymers capable of catalysis and replication. In this approach we allow complexity and information transfer between systems to bootstrap the assembly of systems capable of exhibiting evolutionary dynamics. By developing a new paradigm for evolution outside of biology, we propose a roadmap to engineer the emergence of the minimal evolvable inorganic chemical entities that could eventually make the transition from dead to living matter. This new experimental approach not only requires developments in information theory, but automation of experiments, robotics, and evolutionary programming. Thus this area defines an intrinsically multidisciplinary field requiring contributions from chemistry / chemical engineering, molecular biology / genetics, robotics and computing science. Success could mean new hints to the origin of life on earth as well as the possibility of developing new types of artificial life based upon chemistries not found in biology today.

Introduction

What is life? How did life start on planet earth and how hard was the process to get going? Also, can we engineer totally new types of life forms based upon a different 'chemistry set'? These are fantastic questions that continue to capture the imaginations of many researchers but we wanted to go further and ask if it is possible to create life in the laboratory from scratch on a reasonable time scale. Indeed how would an experimentalist go about it and in what form?

To answer this, in our laboratory we are currently developing a new conceptual approach to engineer evolution outside of biology, inspired by recent work (Joyce 2012; Kauffman 2011; Deamer et al. 2011). We will then use this to develop an experimental framework to test the evolution first hypothesis. We anticipated that this research will lead to the search for minimal evolvable inorganic chemical entities using a series of experimental platforms. This is because minimal self-assembling inorganic systems capable of catalysis and replication may provide a route to cross the information threshold where the number of evolvable bits (Evb) exceeds that required to start the process (Ib). Ultimately this approach could allow us to (re)discover biology relevant to life on earth

as it is today, or to develop a totally new 'inorganic biology' (Cronin 2013). Similar to Joyce (Joyce 2012), we think that the evolvable pre-biotic inorganic systems could be considered to be minimal life forms where Evb>Ib and could therefore represent a testable approach to explore plausible inorganic 'origins' relevant to the emergence of life on Earth, as well as allowing the engineering of new biologies from the bottom up (expanding the possible interplanetary chemistries capable of life). In this context we consider life to be a replicative population-based ensemble of unstable entities, capable through evolution of giving a fitter population as a function of generations capable of survival. Such entities, through generational survival, naturally acquire information content with a measureable increase in functional 'bit-content' (at least initially). Our intention is that this will provide a roadmap to progress towards the complexity of contemporary biological systems whereby the key step is the transition to evolvability, and then ultimately to open ended evolution, see Figure 1.

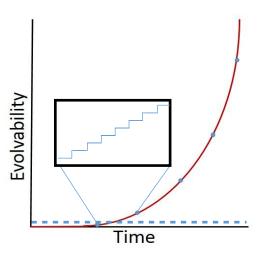

Figure 1. Graph depicting the emergence of evolution with graph of evolvability against time. One of the big questions is the nature of any event / transition in terms of the individual steps needed to be taken to lead to evolutionary chemical systems.

The Roadmap

Although we have many possible starting points for this project, the issues about timescale, evidence of success, a testable theory, and architecture of the chemical search engine are all currently rather challenging. In our work we have been inspired to develop a roadmap that will lead to the establishment of this endeavor in our laboratory over the next years, including:

- 1) A theoretical description of the minimal evolving inorganic system produced by making the 'transition to evolution'. This will define the boundary conditions on the number of operations, information content of the chemical system, and observable behaviour predicted enroute to autonomously evolving chemical systems.
- 2) A chemical map, best described as a chemical network allowing nodes of interacting molecules to be transformed by chemical reactions (connecting the nodes), in inorganic space, along with a language to define and interrogate the map.
- 3) Engineering of hardware allowing the chemical network to be explored. This requires modular plug and play reactor units with well-defined inputs (chemicals, physical control, on board logic and analytical sensors), well defined outputs, and operations resulting from the network analysis.
- 4) Construction of the massively parallel chemical array integrating the network language from (2), the hardware from (3), and the use of theory developed in (1). Over the chemical array, a series of chemical search algorithms will implemented in the search for evolvability.

Ultimately we aim to engineer a minimal chemical cell that can undergo evolution by the process of metabolism, growth, replication, and selection of the fitness through, and feedback of, trillions upon trillions of interactions. The aim will be to 'evolve' through the universe of chemistry, and discover a minimal chemical entity that can emerge as the first candidate for a truly artificial / minimal life form.

Abiotic Evolutionary Chemical Engine

To start to address this grand roadmap in our laboratory we have recently developed a programmable fluidic system comprising a series of linear flow systems, coupled network reactor arrays with a sensor array, and control actuation (Cronin 2012). In this research, by coupling separate reactions in both space and time, we aim to control the assembly of kinetically unstable structures that are maintained away from thermodynamic equilibrium. In a nutshell we will use a fully automated semi-batch-semi-flow system to explore the non-equilibrium assembly of inorganic structures, combinatorial organic reactions combined with gradients of light, pH, redox, organic cations selecting for

catalysis, emergence functionality and persistence of morphology, see Figure 2.

Thus, by generating a vast population of chemical inputs, stochastic chemical reactions, followed by an assay that will allow selection and feedback, the aim will be to develop a new paradigm for evolution outside of biology. The system will use evolutionary programming algorithms to search the chemical space. The aim is to utilize an evolutionary process to boot-strap the discovery of minimal inorganic chemical cells (ichells) capable of evolutionary dynamics. This will require new developments in high throughput chemistry, screening, computational technology, and theoretical developments to adequately set the test question. In effect, this chemical search engine will aim to cover, using advanced algorithms, a chemical space similar to that which was available on planet earth before and during the onset of life, as well as exploring other plausible chemical universes for alternative and new biologies based upon an entirely new and unexpected chemistry set. Our hypothesis is that, by engineering the minimal chemical entity that can undergo evolution autonomously in a given environment, we will provide a new and exciting route to understanding the origin of life as well as new artificial life forms with novel chemistries.

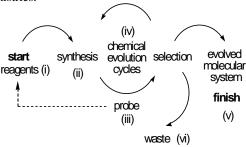

Figure 2. Chemical Evolution Reagents (i) are added to custom reactors (ii) and the results are measured with a probe of sensor arrays (iii). Evolutionary algorithms dictate whether to continue reaction cycles (with or without additional inputs), to collect the material (v), or to eject it to waste (vi). Multiple such modules are put in series and parallel for complex explorations and metabolism engineering will be done using flow control, as well as embedded redox active reagents setting up electrical and proton gradients.

By focusing on the transition region between dead and living matter it is hoped that this vision will attract an unprecedented range of collaborating scientists all unified by the grand vision of creating life in the lab.

Acknowledgments. I'd like to acknowledge my research group, past and present (see www.croninlab.com) as well as our collaborators, colleagues, and many funders in particular the EPSRC whose funding has made this research possible.

Evolutionary Dynamics

Evolution of Frequency-Dependent Sexual Selection Using Agent-Based Model

Atsuko Mutoh, Shohei Kato and Nobuhiro Inuzuka

Nagoya Institute of Technology, Japan atsuko@nitech.ac.jp

Abstract

Nonindependent mate choice occurs when a female is influenced in her choices of mate by the social environment. Frequency-dependent selection (FDS) is a typical example of a nonindependent mate choice and comes in two forms: positive or negative. In the positive form, any rare variant is at a disadvantage, whereas rare variants are favored in the negative form. Both forms of FDS have been confirmed in many species, and several mathematical and theoretical biology studies have reported the advantages of each. However, few studies have focused on the evolution of the two forms of FDS together. In this work, we simulated FDS using an agent-based model consisting of imported mating strategy as gene and female preference influenced by the social environment as meme. Experimental results revealed a relation between the operational sex ratio of males and the FDS strategy of females. A similar tendency was observed among real an-

Introduction

Most models of sexual selection assume that females exhibit a genetically based preference for males with specific traits (Kirkpatrick and Ryan, 1991). However, female mate choice is a complex process involving not only genetic but also nongenetic factors (Westneat et al., 2000). There is increasing evidence that social factors have an important influence on mate-choice decisions (Witte and Noltemeier, 2002). Numerous studies have reported that social environment may influence mate preferences.

Individuals usually mate with opposite-sex others based on their own assessment of the suitability prospective mate, but this assessment can also be modulated by observing the decisions of others, so-called nonindependent mate choice (Vakirtzis and Roberts, 2010). One example of nonindependent mate choice is frequency-dependent selection (FDS). Positive FDS is a form of selection in which genotypes are favored when they are common and negative FDS is a form of selection in which genotypes are favored when they are uncommon (Hughes et al., 2013). Many experimental studies have confirmed positive FDS and negative FDS in nature separately (Singh and Sisodia, 2000; Vakirtzis, 2011).

There are also many studies on FDS using agent-based models in the fields of artificial life. Kawata et al. have examined the possibility of speciation without viability selection by positive FDS (Kawata and Yoshimura, 2000), and Kokko et al. have investigated how negative FDS evolved (Kokko et al., 2007). Some studies have demonstrated the advantages of mate-choice copying (Sirot, 2001; Dubois, 2007). However, these studies are tightly focused and there is no research on both positive and negative FDS for mate choice, together.

Guppies are known to copy the mate choice of other females (Dugatkin, 1992), and has been said that such matechoice copying produces positive FDS (Kirkpatrick and Dugatkin, 1994). However, there have been cases in which guppies have exhibited negative FDS behavior (Hughes et al., 2013). This indicates that different forms of FDS occur in the same species. We expect that the FDS strategy is dictated by the individuality of the agents. Servedio and Kirkpatrick have shown that the mate-choice copying is hereditary (Servedio and Kirkpatrick, 1996), and Dubois defined the copier female and non-copier female to choose a mate by nature (Dubois, 2007). In this work, we propose an agent-based model for both positive and negative FDS to study how to evolute.

Until now, we have expressed inborn bodily characteristics as genes and acquired preferences as memes. In the previous work, we configured an evolutionary model of artificial life (agents) that combine genes and memes and observed their influence on changes in preferences concerning mate selection (Tokuhara et al., 2005; Mutoh et al., 2010). In this paper, we propose a model that adds genes expressing the mating strategy of the female in order to determine how social factors influence female mate choice. By doing so, we can computationally observe mate selection behavior by agents and discuss the evolution of mating strategy on the basis of agent responses to the environment as generations proceed. Finally, we compare our proposed model with 32 kinds of real animals.

Agent Model

We have previously described an enhanced Lerena model (Lerena, 2000) in the form of an agent-based model consisting of both hereditary traits (genes) and acquired traits (memes) (Tokuhara et al., 2005; Mutoh et al., 2010). The concept of memes was proposed by R. Dawkins (Dawkins, 1989), who defined a meme as both a base factor and a unit of cultural information. Our agent model was able to represent constant (i.e., hereditary) and variable (i.e., acquired) information as genes and memes, respectively. However, previous models had no individual difference to change their memes. In this paper, we describe a new model that reflects the concept of FDS and how to change memes is decided by their genes.

Agents

An agent a_i consists of sex sex_i , age aqe_i , dyad genes $qene_i$, and meme $meme_i$, as

$$a_i(sex_i, age_i, gene_i, meme_i).$$
 (1)

Genes are hereditary. The first one is for inborn gene traits and the second for newly added ones related to mating strategy. Memes relate to preferences for gene traits.

$$gene_i = (g_i^{trait}, g_i^{strategy}),$$
 (2)
 $meme_i = meme_i^{pref},$ (3)

$$meme_i = meme_i^{pref},$$
 (3)

where g_i^{trait} is a gene trait of an agent a_i , $g_i^{strategy}$ is a mating-strategy gene of an agent a_i , and $meme_i^{pref}$ is the preference of the q^{trait} in mate choice. The expression of the mating-strategy gene and meme preference is limited to females ($sex_i = female$) and the expression of the gene trait is limited to males ($sex_i = male$). For the sake of simplicity, we set the trait of each male to be fixed throughout his life; that is, males do not have a meme trait.

Mating-strategy genes

We think that common males likely to be popular males. This is because it is easy for popular males to leave offspring. We assume that whether a female prefers popular or unpopular males is decided by her hereditary gene; that is, her mating-strategy gene.

We assume a gene $g^{strategy}$ encoded by bit-strings that determine the mating-strategy of females but is not expressed in males. The length of strings is one bit (0 or 1). When the $g^{strategy}$ of a female agent is one, her matingstrategy is positive FDS, which means she prefer males with popular traits. Conversely, when the $g^{strategy}$ of a female agent is zero, her mating-strategy is negative FDS, which means she prefers males with unpopular traits. We describe later how to discriminate between popular and unpopular

As mentioned above, we represent individuals having traits and mating-strategies as genes and preferences as memes.

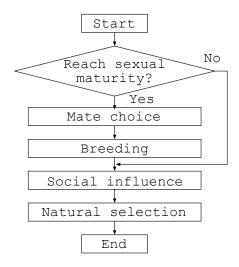

Figure 1: A flow of agent actions during each step.

Action

A single run for each step is mostly a repetition of the following three procedures:

- 1. Mate choice
- 2. Breeding
- 3. Social influence

A flow of agent actions is shown in Figure 1. First, each female reaching sexual maturity selects a male mate on the basis of her preference. Males and females whose mates are determined by mate choice then breed. After breeding, the mate preference of each female is influenced by social environment. This means that the meme preference of each female is rewritten. Finally, agents reaching life end are removed from the population and a certain number of agents are randomly picked to form the next step, which mirrors the process of natural selection. For simplicity, the energy consumed by each action and the fitness used in selection process are not considered. Next, we explain each action in detail.

Mate choice A female a_i selects the best-matched male a_i as a mate from L sampled males. The sampled population consists of randomly selected L males. The female evaluates a male by calculating the hamming distance between her own preference and the traits displayed by the male. The evaluation value $P_{i,j}$ for mate choice is determined using agent a_i 's meme preference $meme_i^{pref}$ and agent a_j 's gene trait \mathcal{G}_{i}^{t} as

$$P_{i,j} = H(meme_i^{pref}, \mathcal{G}_i^t), \tag{4}$$

where H(A, B) is the hamming distance between A and B. Agent a_i prefers a_j to a_k when $P_{i,j} < P_{i,k}$. Among L males, a female a_i chooses a single mate a_j , where $P_{i,j}$ is smallest. Male choice tactics is based on a method (Kawata and Yoshimura, 2000) that is a reasonable assumption for real animals (Gibson and Langen, 1996; Widemo and Sæther, 1999). After choosing a mate, a female a_i is added to the $potential_mate_j$ list for selected male a_j . A male decides on N females randomly in the $potential_mate_j$ list after all females have selected a single mate.

A male can breed with N females per step. When the sex ratio between males and females is equal, we can explain N as the operational sex ratio (OSR) (i.e., the ratio between sexually active males and females in a population) of males. From now, we call N the OSR of the males.

Breeding Suppose that female a_i selects male a_j each other. A new agent a_l is produced as the child of a_i and a_j . This new agent a_l has the following composition.

$$a_l(sex_l, 0, (g_l^{trait}, g_l^{strategy}, meme_{DV}^{pref}),$$
 (5)

where sex_l is either male or female with an even probability; age_l is zero; genes $(g_l^{trait}, g_l^{strategy})$ are determined by genetic operations of Equation (6)(7).

$$g_l^{trait} = mutb(crb(g_i^{trait}, g_j^{trait})),$$
 (6)

$$g_l^{strategy} = mutb(crb(g_i^{strategy}, g_j^{strategy})), \qquad (7)$$

where mutb(A) is a mutate-function that reverses each bit of A with probability γ ; crb(A,B) is a cross-function that returns either A and B with an even probability. Meme is not inherited from parents. Thus, its default is $meme_{DV}^{pref}$.

A female a_i is limited to only one round of breeding for each step. On the other hand, a male a_j is limited to N round of breeding with females in his $potential_mate_j$ list for each step.

Social influence Next, the preference of a female a_i is influenced by the social environment. This means that a female a_i prefers the trait g_k^{trait} of a male a_k who is the most popular or unpopular as indicated by mate choice from other females. That is, a female a_i imitates the gene trait g_k^{trait} with her meme preference $meme_i^{pref}$. Females judge whether a male is popular or unpopular by the number of females in his $potential_mate_i$ list. The mating-strategy gene $g^{strategy}$ is encoded by a bit-string with a length of one bit. Specifically, when the mating-strategy gene $g_i^{strategy}$ of a female a_i is zero, her imitation target is the male agent whose *potential_mate* list has the least number of females in L males selected randomly from a population. Conversely, when the mating-strategy gene $g_i^{strategy}$ is one, her imitation target is the male agent whose potential_mate list has the most number of females in L sampled males.

Here, a female a_i can change her $meme_i^{pref}$ by reversing multiple bits in her bit string data to come close to the gene trait g_k^{trait} of target male a_k . The number of reversing bits is randomly spread over half the total number of all bits.

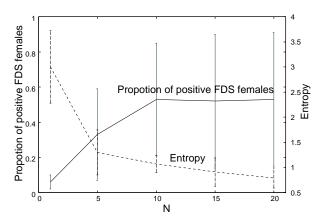

Figure 2: The average proportion of positive FDS females and the entropy of male traits after 3,000 steps at each OSR of males (N) for 40 trials.

Experiments

Next, we describe our experiments with the proposed model, where many male and female agents exist and are evolvable.

Experimental settings

All females can breed after 2[step], and select a mate described above. All parents produce two offspring for each breed. All agents are dead after 20[step] (life time). An initial population of 1,000 agents, consisting of 500 females and 500 males, is evolved from an initial state where: (1) gene g^{trait} and meme $meme^{pref}$ are encoded by bit-strings; the length of these strings is 10 bits each; (2) the initial values of genes g^{trait} and $g^{strategy}$, and meme $meme^{pref}$ are given randomly to all agents. In each step, 1,000 agents are randomly picked to form the next step. The parameterization used in these sets of simulation runs is (1) mutation rate $\gamma=0.01$; (2) simulation steps =3,000; (3) the number of sampled males L=40.

In the experiments, we focus on the transition of matingstrategy genes and the gene diversity of male traits. An alternative approach to summarizing and forecasting gene diversity can be based Shannon's entropy (Shannon, 2001). Gene diversity E is calculated as

$$E = -\sum_{i=1}^{S} p_i \log_2 p_i,$$
 (8)

where p_i is the occurrence probability of ith agents that have the same gene trait in a population and S is the number of gene traits patterns.

Results

We changed the OSR of males, N, in the range of $1 \le N \le 20$ and studied the evolution of the mating-strategy gene. Figure 2 shows the average proportion of female agents

whose mating-strategy is positive FDS and the average entropy of male traits at each N. Results showed that as N becomes larger, the proportion of positive FDS females becomes higher and comes nearer to 0.5. The entropy of male traits becomes lower as N becomes larger.

Discussion

As mentioned above, a female is added to the $potential_mate$ list of a male selected as a mate. A male can breed with N females in his $potential_mate$ list per step. When the number of females in his list exceeds N, some of the females cannot breed. The mating-strategy genes of females failing to breed then decrease at the next generation. The point here is that the mating-strategy of a female preferring a male whose $potential_mate$ list exceeds a breeding capacity (N) is disadvantageous in terms of survival.

The proportion of positive FDS females in Figure 2 becomes higher as N becomes larger. We assume this is because, as N becomes larger, 1) it is harder for the number of females in a male's $potential_mate$ list to become more than N, 2) females leave offspring more easily despite of preferring popular males, and 3) it is easy to increase the mating-strategy genes of preferring popular males; that is, the proportion of positive FDS females becomes higher. Conversely, as N becomes smaller, 1) it is easier for the number of females in male's $potential_mate$ list to become more than N, 2) females preferring popular males have a harder time leaving offspring, and 3) it is easy to decrease the mating-strategy genes of preferring popular males; that is, the proportion of positive FDS females becomes lower.

Also, as shown in Figure 2, the proportion of positive FDS females comes nearer to 0.5 as N becomes larger. This is because the mating success of females approaches 100% regardless of female mating-strategy as N becomes larger. This means that the incidence of positive or negative FDS is irrelevant.

Effect of number of males sampled for female choice

Next, we changed the number of males sampled for female choice, L, in the range of $5 \le L \le 60$, and studied the resulting evolution of the mating-strategy gene. The OSR of males (N) is fixed to one. Figure 3 shows the average proportion of female agents whose mating strategy is positive FDS and the average entropy of male traits after 3,000 steps at each L sampled males for 40 trials.

Experimental results showed that as the size of the males sampled (L) became larger, the proportion of positive FDS females became lower and the entropy of male traits became higher. This is because it was easy for the sampled males to overlap as the sample size becomes larger. Duplicate sampling caused concentration of popularity. Then, as mentioned above, it was easy for the number of females in

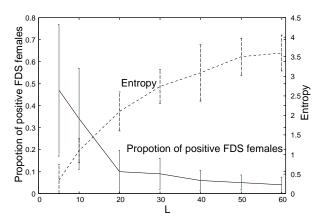

Figure 3: The average proportion of positive FDS females and the entropy of male traits after 3,000 steps at each L sampled males for 40 trials.

a male's $potential_mate$ list to exceed his capacity and the proportion of positive FDS females became smaller.

Inversely, as the size of sampled males became smaller, the proportion of positive FDS females became higher, approaching 0.5. This means that the incidence of positive or negative FDS is irrelevant, since as the size of sampled males becomes smaller, there seems to be no effect of the FDS. FDS only exhibits an effect for animals with a large enough number of sampled males.

Comparison with real animals

In this section, we compare the experimental results with real animals. According to Singh et al. (Singh and Sisodia, 2000), negative FDS has been observed in 14 kinds of animals (parasitic wasp, flour beetle, etc.) while the matechoice copying has been observed in 25 kinds of animals (sailfin molly, Japanese medaka, etc.) (Vakirtzis, 2011). Here, we treat mate-choice copying as positive FDS, since mate-choice copying has been shown to produce positive FDS (Kirkpatrick and Dugatkin, 1994).

The operational sex ratio (OSR) is an important environmental factor that influences mating behaviors (Clutton-Brock and Parker, 1992). We consider the OSR of each mating system. The OSR in monogamous species is approximately equal (Zug et al., 2001). The OSR in polyandrous species is typically strongly female biased (Schamel et al., 2004) while that in polygynous species is male biased (Jorgensen and Fath, 2008). The OSR in promiscuous species is not clear, but it might be male biased since males might have relatively higher potential reproductive rate than females. Then, we can explain the OSR of males as Polyandrous < Monogamous < Polygamous, Promiscuous.

Figure 4 shows the number of species having been confirmed to practice FDS at each mating system. White and black boxes indicate the distribution of 11 species exhibiting

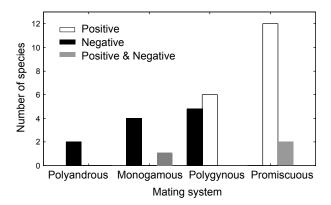

Figure 4: Number of species having been confirmed to practice FDS at each mating system. White boxes indicate positive FDS. Black boxes indicate negative FDS. Gray boxes indicate 3 species exhibiting both positive and negative FDS.

only positive FDS and 18 species¹ exhibiting only negative FDS, respectively. Gray boxes indicate the distribution of 3 species (guppy, drosophila, and humans) exhibiting both positive and negative FDS. In this figure, we can confirm that positive FDS occurs only in species whose OSR of males is large whereas negative FDS occurs in species whose OSR of males is small. This result partially matches our experimental results in Figure 2.

Several experiments (Doucet et al., 2004; Slagsvold and Viljugrein, 1999) and studies (Vakirtzis and Roberts, 2009, 2010; Dubois, 2007) have argued that mate-choice copying is highly unlikely to evolve in monogamous species due to the increasing costs of female competition. The OSR of males belonging to monogamous species is less than that of polygamous males. Our experimental results showing that as the OSR becomes smaller, the positive FDS females becomes lower, confirm these hypotheses.

On the other hand, the number of sampled males (L) of real animals is not clear. We still need to clarify whether the experimental results agree with the behavior of real animals.

Conclusion

We proposed a new model for mate choice involving genes and memes that introduces mating-strategy genes. The mating-strategy gene means that females prefer whether popular or unpopular males. We expressed female agents that have the mating-strategy gene and the meme preference influenced from other mate choice. The results of experiments using our proposed model demonstrated that as the operational sex ratio (OSR) of males becomes larger, the number of positive FDS females increases. A similar tendency was observed among real animals. We also discov-

ered that as the size of males sampled for female choice became larger, the number of positive FDS females decreased. However, we have not matched the results of this experiment against real-world animals. We need to examine the number of sampled males of actual animals and compare it with our experimental results.

We would like to point out here that despite strong evidence for the negative FDS, the evolutionary processes that account for its prevalence are not known (Hughes et al., 2013). From the results of experiments using our proposed model, we can build two hypotheses for this question. One, the OSR is not strongly male biased. Two, the sampled male size is too big.

However, mate choice in the real world is not as simple as in our model. There are a variety of factors involved in propagation, such as cost, fitness and asymmetry in the roles between males and females. We need to consider the existence of male meme traits such as decoration and mimesis. In our future work, we will improve the model based on the findings of this paper so that it better conforms to the real world.

Evolution of Communication in Mate Selection

Aditya Rawal¹, Janette Boughman² and Risto Miikkulainen³

Abstract

A computational study is conducted to evaluate the hypothesis that mate selection is the evolutionary origin of communication. A population of neural networks is evolved for two cooperative tasks - mate selection and prey capture. Simple codes developed for mate selection serve as an effective stepping stone for prey capture but not vice versa. Mate selection followed by an additional prey capture task is also easier to evolve than both together from the beginning. This result suggests that mate selection may be a first step in the evolution of general communication systems in nature.

Introduction

An important scientific question is to understand the evolutionary origin of language. Communication in nature is believed to have emerged through several stages (Corballis, 2011; Searcy and Nowicki, 2010; Bradbury and Vehrencamp, 2011). Initially, non-signals (neutral traits/natural cues) like breathing patterns and urination were ritualized as courtship signals and territorial markings, respectively (Smith, 1997; Hinde, 1997). Next, complex social and environmental pressures required individuals within a group to cooperate and compete in diverse environments (Nowak and Krakauer, 1999; Corballis, 2011). Such interactions gradually lead to more complex signals, and eventually to a protolanguage (Bickerton, 1990). Subsequently, signals developed for a specific evolutionary purpose were exapted and used for other functions (Logan, 2008; Gould, 2002). These steps are believed to have been crucial in the evolution of human language.

Without direct evidence, it is difficult to verify that these steps indeed took place, and to identify the actual behaviors involved. However, simulating language evolution using modern computer science tools can be insightful. Through simulated experiments, this paper evaluates the hypothesis that mate selection is the evolutionary origin of communication. Because mate selection is essential in sexual organisms, is closely related to fitness, and is a social interaction, it is a compelling candidate. During mating, communicative signals emerge naturally to help identify suitable mates. As

soon as such signaling is possible, it may be exapted to serve other social behaviors as well.

In this paper, a series of computational evolution experiments are performed to simulate the origins of mating signals and their exaptation for other social tasks. Communication is evolved in a population of artificial agents in two cooperative tasks: mate selection task and prey capture. In nature, communication during the mating process is used to discern suitable partners and successfully realize reproduction to produce fit offspring (Hauser, 1997). Analogously, during simulated mating, a pair of randomly selected agents from the population exchange signals and determine their compatibility. Initially, this process is based on direct display of traits. In the second phase, simple codes emerge that encode these traits. These codes can be seen as vocal/visual gestures used by individuals in nature.

In the third phase, the successful population from the mate selection experiment is evaluated in an additional task - prey capture. This task requires a more sophisticated communication mechanism on the part of agents in order to time their attack to capture the prey. They can leverage the communication abilities developed for mate selection and quickly achieve the prey capture goal. This adaptation turns out to be computationally faster than evolving communication for prey capture first, or evolving for both mate selection and prey capture at the same time. The experiments thus demonstrate that complex signaling in tasks like prey capture could have been exapted from a simpler task such as mate selection. The computational results thus support the theory that mate selection is the origin of communication.

Prior Work

Although several prior computational studies demonstrated the evolution of communication in intelligent agents, most did not focus on possible biological origins of this process. The environments and tasks were carefully crafted so that communication was necessary for the agents to be successful, and the focus was simply on developing a common communication code (Nolfi and Mirolli, 2010; Steels, 2003, 2005; Tuci, 2009; Werner and Dyer, 1990; Rawal et al.,

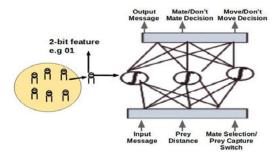

Figure 1: **Population of Agents** - Each agent in the population consists of a 2-bit feature and a feedforward neural network. The feature is required during mate selection to determine agent compatibility, and the network implements the behavior of the agent.

2012).

(Mirolli and Parisi, 2010) studied the role of kin-selection in the emergence of the first signalers and receivers. (Quinn, 2001) demonstrated how simple behavioral cues can be selected by evolution and subsequently used as signals. (Greeff and Nolfi, 2010) evolved implicit and explicit signaling between a team of foraging robots, demonstrating that . Importantly, the individuals in these experiments are homogenous i.e a single genotype is cloned to generate a team. This design makes the task of evolving a common code easier. In contrast in nature, although communicating individuals do share a common code (i.e they have a common agreement on the meaning of the signals) their individual characteristics like size, strength and speed vary. Therefore, a heterogenous population of neural networks is evolved in this paper. An important result is that even with such heterogeneity, a common encoding scheme emerges.

(Mitri et al., 2010) highlighted the importance of group selection in the evolution of honest signaling. Similarly, the experiments designed in this paper are cooperative i.e the team fitness reward is equally distributed between the participants.

The paper is organized as follows. The experimental setup is described first, including the network architecture and the two tasks, mate selection and prey capture. This section also explains the two cooperative tasks - mate selection and prey capture. The results of the five experiments - explicit and implicit communication in mate selection and the three ways of evolving communication for the two tasks - are then presented. The computational and biological insights and future extensions to competitive mating are discussed in the end.

Experimental Setup

A common network architecture is evolved to perform both the tasks of mate selection and prey capture, as described below. Each individual agent consists of a neural network and a 2-bit binary feature (See Figure 1). The 2-bit feature is

Features	0 0	01	10	11
0 0	1	0	0	1
0 1	0	1	1	0
10	0	1	1	0
11	1	0	0	1

Figure 2: **Feature-Compatibility Matrix** - Compatibility of any two agents is determined by the compatibility of their 2-bit features. An entry of one in this matrix indicates that the two features are compatible and a zero indicates that they are not.

used during the mate selection task to determine whether the agents are compatible or not. The neural network controls the behavior of the agent during simulation.

Neural Network Architecture

An agent's neural network consists of a single hidden layer with 10 hidden neurons and four output neurons. The first two output neurons are used as the output message of the agent. The third output is used during mate selection task to indicate mating decision i.e mate/dont-mate. The fourth output is used during prey capture task to indicate agent movement decision i.e move/don't-move. All nodes have a sigmoidal non-linearity and therefore the output value of each node is a real number ranging between 0 and 1. The output node values are rounded off to 0/1 before being used.

In each experiment, there are at least four input neurons - two messaging inputs for receiving messages from other agents, one prey-distance input for sensing prey (integer values between [0-2] and set to -1 during mate selection) and one task-switch input to indicate the type of current task (1 during mate selection and 0 otherwise). In Experiment 1, there are two additional network inputs that provide the agent its own feature value. The network architecture is fixed over the course of evolution. At the start of simulation, a population of 64 agents is generated with random neural network weights and a random 2-bit feature. During each evolutionary generation, 3000 trials of a given experiment are performed on a pair of randomly selected networks. Binary tournament selection is used to select parent population. To generate the offspring population, the neural network weights of the parent population are mutated with a probability of 0.4 by adding a Cauchy-distributed random value to it. Note, that the 2-bit feature value associated with each agent is not mutated and is directly transferred from parent to offspring.

Two cooperative tasks are used to evaluate the population - mate selection and prey capture as described below.

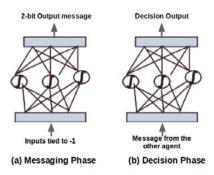

Figure 3: **Agent Behavior** - The agents implement their mate-selection and prey-capture behavior through two network activations: (a) Messaging Phase - The network input nodes dedicated to receive messages are tied to a constant value of -1. In mate selection, they output a code for their 2-bit feature. In prey capture, they output a 2-bit code for distance to the prey. The 2-bit message is then given to the other network as input. (b) Decision Phase - The networks are activated and their output decision node value is rounded off to give a 0/1 decision (mate/don't mate or move/don't move. In this manner, the networks communicate their states first and then decide upon a proper action to take.

Mate Selection Task

During the mate selection process in nature, males often try to communicate their characteristics through simple cues, gestures and more sophisticated signaling (Stoffer and Walker, 2012; Johansson and Jones, 2007). These signals convey the fitness of the individual (and therefore fitness of a future offspring) and thus influence the prospects of mating with the female.

The mate selection task emulates this process. A 2-bit feature associated with an agent represents its individual characteristic in this artificial setting. For simplicity, the population is not divided into males and females. Instead, two agent networks are randomly selected from the population and they exchange messages to make a mate/dont-mate decision. The ground truth for this mating decision is predefined in a randomly generated feature-compatibility matrix. One example of such a matrix is shown in Figure 2. A 1 in the matrix indicates that the two agents are compatible while a 0 indicates that they are not. From a biological perspective, compatibility between two agents can be viewed as the fitness of their offspring i.e if two highly compatible agents decide to mate, their offspring will have a higher fitness than the offspring of two incompatible agents.

Such a mating task is cooperative in that none of the agents receive fitness increment unless both of them make the correct mating decision. Both agents receive a fitness increment of one for each correct mating decision. For example, feature values 01 and 10 in Figure 2 are compatible and therefore two agents with these features receive a fitness

increment of one if both decide to mate and zero if otherwise.

During this task, the task-switch and prey-distance inputs are set to constant values of 1 and -1, respectively. Each trial consists of two phases (Figure 3). In the first phase (defined as the messaging phase), the two neural networks are activated (with messaging input tied to constant value of -1) and the first two output nodes are sampled for their values. The two output real values are then rounded off to obtain a 2-bit output message. In the second phase (the decision phase), this 2-bit output message from one network is given as messaging input to the other network. After a second network activation, the value at the output mating decision node is rounded off to generate a mate/dont-mate decision.

Note that in the current simulations the two paired networks do not undergo actual mating (i.e crossover) based on their mating decision. Instead, offspring is generated through mutations of most fit parents. This simplification helps focus the study on the question of how mate selection may act as an origin for communication. However, to this end it is essential that the agents are not artificially constrained to generate any specific message type during the messaging phase. The only feedback the agents receive (indirectly, through fitness) is based on the correctness of their mating decision.

An additional constraint is added to ensure that each feature is equally represented in the population over the course of evolution. The initial population of size 64 is divided into four sub-groups of size sixteen each - one group for one feature type. After all networks have been evaluated in each generation, a binary tournament is performed on each feature group separately to obtain sixteen offspring. Since the parent feature is directly transferred to offspring and is unaffected by mutation, the feature representation in population remains fixed at sixteen. This restriction prevents any feature in the population from becoming dominant (which would remove the need to communicate).

Prev Capture Task

Prey capture in nature often involves cooperation and communication on the part of agents. This task simulates such a scenario with a fixed prey in a discrete, deterministic world. At the start of each trial, two agents (randomly selected from the population) are positioned at random distances apart from the prey (Figure 4). The agent agents can sense the distance to the prey but cannot sense the distance to the other agent. They have two possible actions - either move towards the prey or stay in their current position. With each agent move towards the prey, the agent-prey distance decreases by one. The prey is considered captured when the two agents pounce on the prey in the same time step. In order to be successful, the agents need to communicate when they are ready for the capture.

The task-switch input neuron is set to a constant value

of 0 to indicate prey capture task, and the prey distance inputs to the proper value to indicate distance. Similarly to the mate selection task, each time step in a trial is divided into two phases - messaging phase and decision phase. The output movement decision node of the network determines the agent action: move/dont-move. agent agents receive a fitness increment of one on capturing the prey and zero otherwise. Again, agents are not constrained to generate a specific message type but must evolve one that works.

Measuring Success

In each experiment, data is collected over 150 runs and averaged. Since fitness distribution is cooperative for each task (i.e in a given trial, a pair of individuals receive fitness of one only if both make correct predictions), it is very difficult to achieve 100% population success. Therefore, a population is deemed successful if at least 25% of its individuals have an average fitness of greater than 75% of the maximum fitness. This success criteria ensures that a significant fraction of population develops common communication code to solve the task. The total number of generations required to evolve a successful population is used as a quantitative measure to compare different experiments.

The next section describes the experiments in detail.

Experiments

The first two experiments demonstrate that a common code does evolve in mate selection. Experiments 3-5 then evaluate the hypothesis that mate selection is an effective first step in evolving a more general communication system.

Experiment 1 - Mate Selection with Feature Inputs

In the first experiment, the population is evaluated in the mate selection task. Each agent (in the randomly selected pair) is explicitly provided its own 2-bit feature as input during the messaging phase. The 2-bit message generated at its network output is then given as input to the other agent in the decision phase. In this setting, the neural network thus has four active input nodes - 2-bits for agent feature and 2-bits for sensing the output message of the other agent.

On average after 11 generations, the best agent pair evolve a simple signaling system where they send their exact input feature as a message during the messaging phase. These messages are similar to the explicitly visible characteristic of an individual in nature - for example its size and strength. The messages thus do not represent a communication code; they are simply a direct expression of the underlying characteristic. They serve as a baseline for evolving a communication code.

Experiment 2 - Mate Selection with Hidden Features

In the second experiment the setup is modified to allow an actual communication code to emerge. During the messag-

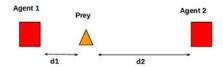

Figure 4: **Prey-capture task** - There is one static prey and two agents positioned random distances ($0 \le d1 \le 2$, $0 \le d2 \le 2$)apart from the prey. At each time step, the agents can either stay still or move one distance unit towards the prey. To be successful, they are required to capture the prey by stepping on its location at the same time step. The agents can sense the prey distance but not the distance to the other agent. Thus, they need to develop a communication system to coordinate their movements.

ing phase, the 2-bit input feature is hidden from the agent i.e not given to the neural network as input. Evolution has to figure out this feature and develop a code for communicating it. Thus, only messaging inputs of the network are active during the decision phase.

On average, after 31 generations, the agent pairs develop to send an encoding of their input features during messaging phase. These encoded messages provide the necessary information to distinguish compatible agents from the not-compatible ones. In certain cases, the encodings are shared between compatible individuals. The encoding evolved for the feature-compatibility matrix shown in Figure 2 is one such case. Since feature values '00' and '11' are compatible with both themselves and each other, evolution discovers a shared message (e.g '00') to recognize these two features (exact code values vary across different runs). In this manner, a true communication system evolved to express the features hidden from the agents. This system can be exapted to other tasks, as shown below.

Experiment 3 - Mate Selection followed by Mate selection and Prey Capture

This experiment simulates how simple communication that was initially evolved for mate selection can be exapted for the more complex prey capture. The population is first evolved for the mate selection task without feature inputs (Experiment 2). The successful population is then evolved in two tasks - both mate-selection and prey-capture together.

During the mate selection task, prey-distance input is tied to a constant of -1 and task-switch input is set to 1. The feature-compatibility matrix shown in Figure 2 is used. Once a quarter of population achieves an average fitness of more than 75% of the maximum fitness in the mate-selection (criteria of success as described earlier), an additional prey capture task is introduced. In each generation, the population is separately evaluated in the two tasks. Fitness of an individual in the population is its average fitness in the two tasks. The input/output communication channels developed

during the mate selection task are reused during prey capture task. The experiment terminates once the population achieves the average fitness goal for both the tasks (i.e quarter of population with an average fitness greater than 75%). During the course of evolution, feature representation in the population is kept constant (as described in the mate selection task).

During the prey capture task, the prey distance input to the network is set according to distance and task-switch input is set to 0. Agents are positioned at random distances from the prey. The maximum initial agent-prey distance is two steps and the minimum distance is one step. Agents can choose to move/dont-move towards the fixed prey by activating their movement output node.

The evolved communication codes become quite sophisticated. When the first agent is at a distance of more than one from prey, it sends a code (e.g '00') signaling that it is moving and has yet to reach next to the prey. At a distance of exactly one step from the prey, it changes its output (e.g '11') indicating that it is now ready to capture the prey. The second agent ignores these signals from the first agent while it is not ready for prey capture (i.e it is at a distance of more than one step from prey), and instead it moves towards the prey. Once the second agent reaches a distance of exactly one step from prey, it starts paying attention to the signal from the first agent. If the first agent is ready for prey capture (i.e it signals '11'), both agents move to the prey location to capture it. Otherwise, the second agent selects the dont-move option and waits until the first agent is ready (outputs '11').

Solution to the first task (mate selection) evolves on average in 31 generations (same as in experiment 2). It takes on average 55 additional generations to evolve a population that solves both tasks. Thus on average a total of 86 generations are required to solve the two tasks together completely. The entire profile of this process is shown in Figure 5

Interestingly, the codes used during mate selection task are reused during the prey capture task. For example, one pair of agents used the code '11' to communicate their own feature in the mate selection task. After evolving in the prey capture task, their descendants used this same code to indicate readiness for prey capture. In addition, they evolved a second signal ('01') to indicate that they were moving towards the prey. In this manner, the mate selection gave them a starting point that was modified for the new task.

Experiment 4 - Mate Selection and Prey Capture Coevolution

In this experiment, communication is evolved for mate selection and prey capture simultaneously. Starting from the first generation, each agent is evaluated in both tasks, and their fitness is averaged across tasks. Thus, a population is deemed successful if it achieves the average fitness goal for both tasks. Feature representation in the population is kept

constant by performing binary tournament selection on each feature sub-group separately, as before.

A successful population evolves on average in 123 generations. As shown in Figure 5, coevolution of both tasks tends to take longer than when mate selection is evolved first. A successful population is evolved on average in 123 generations (vs. 86 generation in Experiment 3; p < 0.066). Thus mate selection serves as a useful stepping stone for other tasks.

Experiment 5 - Prey Capture followed by Mate Selection and Prey Capture

This experiment is similar to Experiment 3, except the roles of mate selection and prey capture are reversed. The population is first evolved to solve the prey capture task and then to solve both mate selection and prey capture. The input/output communication channels developed during the prey capture task are exapted to the mate selection task.

Initially, during the prey capture task, the agent features are irrelevant (since agent compatibility information is not used). Therefore, binary tournament is performed on the whole population irrespective of the feature type. Once a successful population evolves for the prey capture task (again, a quarter of the population performing at 75%), mate selection is introduced as a second task for evaluation. Since mate selection requires information about agent compatibility, 2-bit features are assigned randomly to individuals in the population at that point. Subsequently, binary tournament is performed on each feature group separately as usual in mate selection.

A successful population evolves on average in 183 generations. As shown in Figure 5, exaptation from prey capture to mate selection takes longer than both exaptation from mate selection to prey capture (Experiment 3) and their coevolution (Experiment 4); these differences are statistically significant p < 0.0001). This result suggests that it is not simply the incremental nature of exaptation that matters but the actual steps; mate selection is a better stepping stone for building a general communication system than prey capture is.

Discussion

As shown in Figure 5, it is easiest to evolve a population for the two ecological tasks of mate selection and prey capture, if it is first evolved to solve the mate selection task. A prerequisite for communication includes the ability to output meaningful signals and interpret the received input signals (Mirolli and Parisi, 2010). The mate selection task builds an initial structure to support this mechanism. The signals that evolve for mate selection are simple and fundamental: they map a single state to a single symbol. Once created, this communication mechanism can be be co-opted for more difficult tasks like prey capture, where multiple states must be mapped to the same symbol, or multiple symbols have the

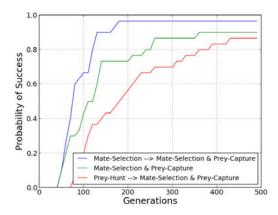

Figure 5: **Probability of success throughout evolution** This graph shows how likely evolution is to discover a successful population (where a quarter of the population is successful 75% of the time in the two tasks of mate selection and prey capture) by a given generation. The most effective method is to evolve mate selection first, followed by additional prey capture. Evolving both at once from the beginning is weaker, but still stronger than evolving for prey hunting first followed by mate selection. Thus, communication evolved for mate selection makes it easier to evolve communication for another task. This result suggests that mate selection is a likely first step in the evolution of communication.

same meaning. Indeed, networks evolved initially for mate selection end up using significantly fewer symbols than coevolved or initial prey-capture networks (with p < 0.001; Figure 6). From a computational perspective, the mate selection task thus provides a better stepping stone to construct general communication than prey capture.

Future Work

The mate selection process in these experiments was cooperative in that both partners aimed at determining compatibility, and there was no conflict of interest. While such mate selection is seen in nature, competitive mate selection is more common (Andersson, 1994). That is, one of the genders, usually female, chooses the mate, and the other gender, usually male, tries to convince that he is a good choice. Competitive mate selection likely originates from the asymmetry in gender roles: Females try to maximize quality and males quantity of their mates. Competitive mating thus leads to behaviors where males may try to communicate dishonestly, exaggerating their quality, and females try to estimate what the males' actual quality is. On the other hand, most other communication between animals is by necessity cooperative. For instance in hunting, the individuals need to communicate honestly in order to be effective. An interesting

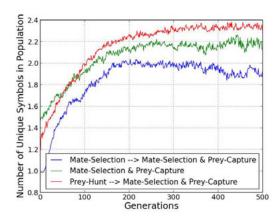

Figure 6: The Number of Communication Symbols Evolved - With prey capture, there are many states when the agent is not ready, and therefore some redundant symbols are likely to evolve to signal these states (e.g 2.4 symbols on average). In contrast, mate selection often results in a one-to-one mapping from states to symbols. Therefore, the final communication system built on mate selection is likely to be simpler (about 2.0 symbols on average) and therefore easier to discover than with the alternatives. The population success criterion was increased from 75% to 90% of maximum fitness in this comparison to reduce variance.

scientic question therefore is: How can an eventually mostly cooperative communication system be built on a competitive origin? This question will be studied in future extensions of the simulations described in this paper.

Conclusion

This paper evaluated computationally the hypothesis that mate selection is the origin of communication in nature. That is, communicative signals emerge naturally to help identify suitable mates; as soon as such signaling is possible, it is exapted to serve other social behaviors, such as prey capture. Computational simulations verified this hypothesis in a simplified setting where direct displays of traits evolved to coded communication of traits, and were then exapted to use in coordinating a prey capture. This sequence turned out to be faster than evolving prey capture first or both together from the beginning, suggesting that mate selection may indeed be an effective stepping stone to construct general communication systems.

Constrained genetic architecture promotes cooperation

Antoine Frénoy¹, François Taddei¹, and Dusan Misevic^{1*}

Abstract

Cooperation in nature often has direct costs but only indirect benefits. Kin and group selection theories comprehensively address its evolutionary origins, but our knowledge of the precise genetic mechanisms that prevent cheater invasion and maintain cooperation is incomplete. Here we review our published work on cooperation in Aevol, an agent-based, in silico genomic platform used to evolve and study populations of digital organisms that compete, reproduce, and cooperate by secreting a public good. Motivated by the observation of phenotypically identical individuals who had radically different evolutionary fates, we recorded and compared gene locations, effectively performing bio-inspired genomics analyses of our digital organisms. We found that the association between metabolic and secretion genes (promoter sharing, overlap via frame shift or sense-antisense encoding) was characteristic for populations with robust, stable cooperation. Such architecture arose de novo during the evolution of cooperation, but only when producing the public good was costly. Effectively, cooperation evolved to be protected and maintained through constrained, entangled genetic architecture. Beyond confirming the importance of second-order selection, we uncover a novel genetic mechanism for the evolution and maintenance of cooperation. Our results suggest a method to limit the evolutionary potential of synthetically engineered organisms, in order to reduce the change or loss of synthetic gene circuits, a major issue in synthetic biology.

Background and Introduction

The evolution of cooperation in microbial populations is a fascinating, rich and controversial evolutionary problem (West et al. 2006). Evolutionary explanations of cooperation are constantly being improved and refined by a host of mathematical tools such as game theory and meta-population models (Lehmann and Keller 2006). However, these methods typically do not distinguish between genotypes and phenotypes and are unable to investigate the structure of genomes that encode the cooperative traits. Microbial studies have already hinted at potential mechanisms by which genetic architecture can affect cooperation, including gene coregulation and pleiotropy (Foster et al. 2004; Dandekar et al. 2012). Here we review our published work (Frénoy et al. 2013) that examines two specific types of genomic architecture: (1) operon sharing, when secretion and metabolism genes are on the same operon and share a promoter and a terminator, and (2) overlap, the base-pair sharing between metabolic and secretion genes possible when genes are in different reading frames or on different DNA

strands. Well described in viruses, overlaps in bacteria are existent but rare. Similar to operons, they are thought to be caused by strong maximum genome size constraints or selection for co-regulation (Normark et al. 1983). However, overlaps have not themselves been studied as an evolutionary constraint, which we do here, in the context of cooperation.

Methods

In our work we used the in silico experimental evolution system Aevol (Batut et al. 2013), heavily inspired by microbial genetics. The implementation of an Aevol digital organism allows for continuous metabolic and cooperating phenotypes. For example, instead of the classical binary cheat/cooperate behavior, there is an infinite number of possible cooperation phenotypes. Individuals live on a grid and when they evolve cooperation, it is via a secreted public good molecule that diffuses and degrades (Misevic et al. 2012). The public good is costly to secrete but may benefit any neighboring organisms. Rules for transcription, translation and protein synthesis govern the complex mapping of a double-stranded binary string (genotype) to phenotype to fitness. Phenotypically similar or even identical individuals can have different genotypes, thus also having different evolvability, robustness, and evolutionary fate (Frénoy et al. 2012). All these properties of Aevol enable the two sets of evolutionary experiments we performed, in which genetic architecture constraints relating to cooperation were both observed and quantified. We first analyzed the dynamics of cooperation loss due to increased cost of secretion (cheater invasion experiments), and then evolved cooperation from non-secreting ancestors, under different costs (de novo evolution of genetic links experiments). To quantify genetic architecture, we identified instances of all operon sharing and overlap between genes. For each of the evolved cooperators we analyzed the architecture of all its secretion genes and classified them in different categories based on presence or absence of gene overlap and operon sharing. Additionally, we constructed millions of random mutants and measured the effect of mutations on both fitness and secretion to confirm the phenotypic effect of the constrained genetic architecture.

Results and Discussion

All experimental results supported the hypothesis of cooperation maintenance via constrained genetic architecture.

(1) Cheater invasion experiments. Using a bank of 50 evolved cooperators, we seeded new populations that continued evolving under a high secretion cost. Although the starting individuals had comparable level of secretion, under the new cost regime, the populations greatly varied in the resistance to cheater invasion. In replicate experiments, some populations consistently preserved low levels of secretion, while others always lost all secretion genes. The abundance of promoter sharing or overlapping between metabolic and secretion genes was a good predictor of cooperation maintenance. Mutational analysis confirmed that the constrained genetic architecture resulted in a greater proportion of cooperation-destroying mutations also having a direct negative fitness effect, than non-constrained architecture. Secretion-decreasing mutations evolutionary dead-ends, resulting in evolvability suppression. possible spontaneously-evolving mechanism maintenance of far-sighted traits (Altenberg 2005). Interestingly, the mutation analysis was a good predictor of short-term evolution, while genetic architecture was better at explaining long-term evolutionary fate of cooperation.

(2) De novo evolution of genetic links experiments. In the second set of experiments, populations starting from non-cooperators evolved under different secretion cost regimes. Cooperators evolved to employ the constrained, protective encoding, and more so when the cooperation cost was high (Figure 1). This confirms that the entangled genetic architecture is subject to selection because of its protective effect on cooperation.

In the work reviewed here, we provide a new set of potential explanations for the evolution of operons and overlaps, both important building blocks of life. Operons and overlaps may help protect genes that are at risk of removal because of a short-term cost and in spite of the long-term benefit they may provide. In the case of cooperation, genetic architecture constraints may be highly relevant to a better understanding of the much-studied siderophore-mediated cooperation in *P. aeruginosa*, where cooperative as well as metabolic traits are under the control of the same quorum sensing mechanism (Dandekar et al. 2012). However, beyond

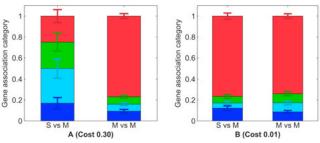

Figure 1. Genetic associations after *de novo* cooperation evolution at different secretion cost (from (Frénoy et al. 2013)). We quantified operon sharing and overlaps between secretion genes and metabolic genes (S vs M) and between metabolic genes and other metabolic genes (M vs M). Four classes of gene pairs were identified: sharing an operon without overlapping (dark blue), overlapping and sharing an operon (light blue), overlapping without sharing an operon (green), not sharing an operon nor overlapping (red). Error bars represent standard error of the mean.

explaining evolutionary outcomes in the field of cooperation, the mechanism we described here could be actively used to prevent mutations from removing the genes introduced into bio-engineering organisms, a major problem in the field of synthetic biology (Sleight et al. 2010; Yang et al. 2013; Renda et al. 2014). We have already designed tools that would allow manipulation of digital genomes in a way that would create or eliminate constrained architecture without changing the phenotype. In ongoing work, we are experimentally testing the effect of overlap on the maintenance of costly genes in synthetic *E. coli* strains, effectively connecting *in silico* and *in vitro* research to practical applications.

Abstract

Predator-prey interactions are one of the most common coevolutionary dynamics in Nature. We consider a model of the coevolution of prey appearance and predator vision, where a successful result is visually apparent. While using a neurophysiologically-based model of vision and a rich developmental process for prey patterning, we show that predatorprey coevolution can maintain engagement. Backgrounds with large regional differences generally lead to prey that appear as mixtures of the regions. Finally, we find that engagement between predators and prey is supported by greater background complexity.

One of the most visually-striking phenomena in predatorprey coevolution is prey crypsis, the ability of prey to avoid detection by predators. Chameleons and cuttlefish take this behavior to the extreme and physically alter their pigmentation to match their environment, which can even be realized synthetically in robots (Morin et al., 2012). However, prey crypsis is often manifested as static pigmentations, such as stationary Turing patterns (Turing, 1952), that are selected for being advantageous in particular environments. Inspired by Bond and Kamil (2002), where blue jays are used to interactively evolve moth phenotypes, we study the effect of background complexity on the coevolution of prey appearance and predator vision.

There is an intimate coevolutionary relationship between predator vision and prey appearance. Visual systems are generally adapted for stimuli that exert selective pressure on the organism, such as food, prey, predators, and mates. Even when visual systems have adapted to attenuate visual signals from their relevant stimuli, there is still the challenge of visual attention. Visual attention can be roughly thought of as a way of prioritizing a visual field based on interest. Improper allocation of visual attention can mean the difference between catching dinner or going home hungry.

In this research we study the coevolution of prey appearance and visual attention in predators. Prey appearance is evolved via genetic programming, such as in (Sims, 1991a; Reynolds, 2011). Predator vision is evolved using a neurophysiologically-based model of visual attention (Itti

and Koch, 2001). We focus on the effects of environmental complexity on this coevolutionary interaction.

Merilaita (2003) shows that greater background complexity can increase prey detection times by predators. In even earlier work on background matching in camouflage, it was suggested that visual complexity may favor color polymorphism, because there will often be many polymorphisms that can achieve similar patterns (Endler, 1984). These and other works focus on camouflage via background matching, but there are alternative forms of camouflage, in particular, disruptive colorations. In contrast to background matching, where an entity attempts to blend in with the background, disruptive and distractive colorations are patterns that attempt to draw the observer away from the pattern. Disruptive colorations have been shown to be an effective tool for camouflage when tested against live predators (Schaefer and Stobbe, 2006; Cuthill et al., 2005). A number of visual properties significant to predator-prey interactions have been identified in these contexts, including background complexity, prey contrast, and object density (Dimitrova and Merilaita, 2010, 2012, 2014). In our model, the capacity for complexity in prey is greatly enhanced by utilizing a developmental mechanism to produce color images of moderate dimensions, as compared to previous work which explores the selective favorability of simple patterns (Dimitrova and Merilaita, 2014) or directly-represented greyscale images (Bond and Kamil, 2002).

In previous work, we have explored the coevolution of predators and prey (Ficici and Pollack, 1996), finding that such systems are often subject to pathologies such as convergence to mediocre stable states (Ficici and Pollack, 1998), loss of gradient, incorrect focusing, and relativism (Watson and Pollack, 1996). Within the ecology literature, predator-prey systems are commonly studied, including analytical and computational models as well as empirical studies. However, analytical models of predator-prey systems can quickly become infeasible for study as the number of species increases. Furthermore, analysis of phenomena such as predator preference runs into difficulty when accounting for alternative food sources under ecological dynamics (van

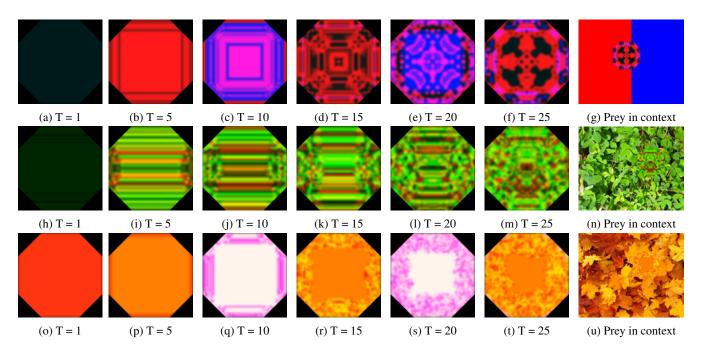

Figure 1: Time-series of prey morphogenesis.

Baalen et al., 2001; Leeuwen and Brännström, 2013).

The pathologies of competitive coevolution can be readily explained in the language of predator-prey systems. Loss of gradient, when one population becomes worse such that it no longer exherts selective pressure on the competing population, or better such that the competing population can no longer maintain engagement. Examples of this would include evolutionary advances in a predator-prey ecosystem where prey can achieve greater escape velocities, leading to diminished returns for predators, and in real ecosystems, probably triggering the predators to seek another food source. Incorrect focusing is when members of one population overspecialize in interactions with specific competitors such that they fail to generalize to other competitive interactions and are prone to extinction. Examples of incorrect focusing are not as common in real ecosystems, where a large number of coevolutionary interactions continually apply selective pressure. In competitive coevolutionary interactions, the quality of an individual is a function of its competitors. This relativism in scoring means that an individual that appears to be more fit to an external observer, may be just as fit as a lower quality individual relative to a given set of competitors. In Nature, this is less of an issue for similar reasons to incorrect focusing, there are continual pressures from many aspects of the ecosystem and environment such that these disambiguations will occur infrequently.

Predator-Prey Coevolution

When simulating predator-prey coevolution, we use a 2-population competitive coevolution model. The prey pop-

ulation consists of a set of genetic programs that encode a generative function for their visual appearance. The predator population consists of a set of numerical weights for a saliency detection algorithm. Prey receive points for not being detected, or causing the predator to incorrectly classify the background as prey. Predators receive points based upon the accuracy of how they perceive the environment.

There are a number of ways to compute the fitness in coevolving populations. We focus on pairwise competitions. Sims uses best v. best competitive coevolution (Sims, 1994), where each population competes against the best individual of the competing population. However, best v. best can lead to incorrect focusing and disengagement by assigning greater fitness to individuals that overspecialize in defeating the champion competitor. Tournaments can reduce the number of comparisons from $O(N^2)$ to O(NlogN), but still represent approximations of a full pairwise competition (Angeline and Pollack, 1993). All v. all competitive coevolution reduces the tendency for focusing, but comes at great computational cost. Nevertheless, we compute the complete payoff matrix via all v. all pairwise competitions to facilitate coevolutionary engagement between all species.

Prey

Prey patterns are produced through a process of algorithmic morphogenesis. The process is much like the standard notions of chemical morphogenesis (Turing, 1952), where a system of reactions determines chemical kinetics while a diffusion system transports chemical species, contributing to pattern formation. However, instead of a standard system of reactions, we employ genetic programming to serve as an

algorithmic chemistry.

The use of genetic programming to evolve images and dynamical systems has been a part of the ALife community since the early years (Sims, 1991b, 1992). These ideas were extended to the evolution of self-constructing and selfrepairing patterns (Miller, 2004). However, much of the work on evolved computer graphics has focused on interactive evolution, perhaps in part because of the complexity of developing a computer vision system capable of scoring images in a meaningful way. The interactive evolution of generative images has recently achieved widespread popularity with the Picbreeder website (Secretan et al., 2011). Of particular relevance to this study is the recent work on the interactive evolution of camouflage (Reynolds, 2011), where a sophisticated texture rendering system is employed to generate patterns for human-guided selection. Finally, alternative biologically-inspired generative representations may be of interest for achieving patterns that may be closer to those of natural systems (Cussat-Blanc and Pollack, 2012).

Genetic programming is an evolutionary method for discovering computer programs (Koza, 1992), where the programs may represent robot controllers, machine learning classifiers, developmental processes, or many other things. The algorithms used to evolve genetic programs are often very similar to those employed by genetic algorithms, with particular exception to how variation is performed. We use the array method of program representation (Koza, 1994) which is most conveniently bounded by program size limits in units of number of nodes (200 nodes for the prey).

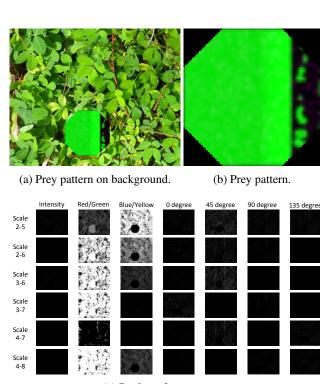

Prey programs are functions of 3 inputs (x, color, and current value) that return a floating point, which are iterated over all color channels at each (x,y) coordinate of the prey, in this case an octagon of radius 41 and (x,y) coordinates are scaled to [-1,1]. This function output is then squished with a hyperbolic tangent. Prey programs can be composed of the following terminal and function set:

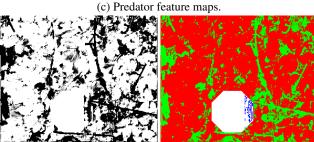

x,color,value,+, -, *, /, iffte, sin, cos, tanh, min, max, abs, hypot, sec, csc, cot, tan, gamma.

Prey are iterated function systems. During each iteration, first the GP program is evaluated once per location and color channel, then a Gaussian filter is convolved with the image as a heuristic pseudo-diffusion. This pseudo-diffusion can introduce artifacts at the boundaries, which we partially alleviate by cropping the prey by a single pixel along the boundary. An example figure can be seen in Figure 1.

Predators

Predator vision is modeled based upon a neurophysiological model of visual attention (Itti and Koch, 2001). Images are broken down into a set of feature maps of intensity, color difference, and orientation, then combined into 42 features taken as differences across multiple scales. Predator genotypes encode weights for each feature map, which are lin-

(d) Predator saliency map.

(e) Predator classification.

Figure 2: Diagram of predator's visual system. 2a shows the prey pattern situated on the grassy background. 2b shows a zoom-in of the prey pattern. 2c shows the weighted feature maps used by an example predator. 2d shows the corresponding saliency map for the feature maps in 2c. 2e shows the same example predator's classification of 2a, where red indicates incorrectly classified background, green indicates correctly classified background, white indicates correctly classified prey, and blue indicates incorrectly classified prey.

early combined into a saliency map. The saliency map encodes the priority of attention at each location in the visual field. We allow the saliency map to take on both positive and negative values, where positive values indicate a prediction of the prey's position. For a more detailed description of the components of the vision model, see (Itti and Koch, 2001).

Saliency-based models of visual attention have a long history in studies of the neuroscience of vision (Niebur et al., 1993; Itti and Koch, 2001; Borji and Itti, 2013). There are now many algorithms for visual attention, some based on

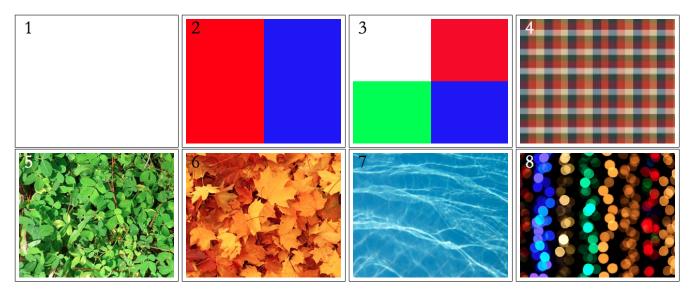

Figure 3: Prey environments used in experiments.

neurophysiology and some engineered for optimality. A comprehensive review of current visual attention algorithms can be found in (Borji and Itti, 2013). We use a bottom-up model based upon (Itti and Koch, 2001), which has been shown to correlate with human eye movements (Parkhurst et al., 2002; Itti, 2005). In the traditional model of Itti, where feature maps are aggregated hierarchically into the saliency map, first by grouping features by type into conspicuity maps, then combining conspicuity maps to compute the saliency map. Our model uses the simplification of combining all feature maps to immediately compute the saliency map.

Evolutionary Algorithm

We use a genetic algorithm for both the predator and prey populations. Individuals are selected with tournament selection using tournament sizes of 3. Selected individuals are mutated (45%), crossed over (45%), or replicated (10%) in the successive generation. Prey are crossed over using standard subtree mutation and crossover (Koza, 1992), while predators are mutated by adding a vector of small Gaussian mutations to the genome and recombined via uniform crossover. The evolutionary algorithm is run for 500 generations in all experiments in this study.

Experiments

We consider a number of environmental backgrounds of varying complexity. We obtained 5 naturally patterned images¹ and created 3 simple images, shown in Figure 3. Images were prepared by cropping regions to a size of 300x240. While a number of methods have been developed

within the computer vision community to characterize image complexity, we report on the JPEG file size. The concept of complexity resides at the heart of the field of data compression, hence our choice to use it as a metric of image complexity. Image sizes in the same order as Figure 3: 446B, 1.3kB, 1.7kB, 14k, 47k, 123k, 93k, and 126k. During simulations prey position and rotation is randomly determined. Prey position is randomly chosen such that the prey resides entirely within the background environment, and rotation is uniformly chosen from all 4 possible 90 degree rotations. 25 independent trials are conducted for each background environment². Due to the computational costs of simulating prey morphogenesis, predator vision, and computing complete pairwise payoff matrices, we use population sizes of 100 for both the predators and prey. The same random seeds are used for each background, such that the initial populations have the same constituents for each random seed, but then quickly diverge as selection and mutation vary the populations. In Figures 4, 5, 6, and 7 we use two colors, red and blue, to indicate data reported for the population average and best individual, respectively.

When measuring the degree of background matching that is present in a given population over evolutionary time, we use the same 42-D feature vector that is used by predator vision. Merilaita and Lind (2005) previously suggested that quantification of background matching in prey can be misleading if it isn't computed with respect to the predator's perception. When measuring the distance between a prey and the background we take the Euclidean distance between the average feature vector of the background image and the

¹Images are public-domain, and are retrieved from http://www.publicdomainpictures.net/.

²Due to computational difficulties, a few runs were incomplete. Complete runs per background (ordered as in Figure 3): 24, 21, 25, 23, 25, 24, 22, 23

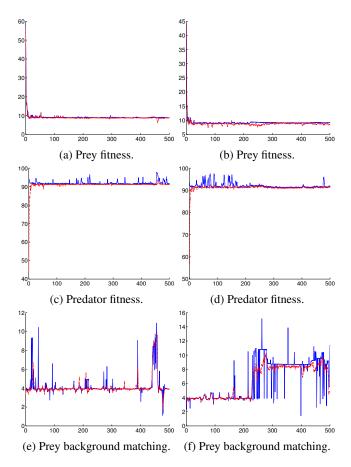

Figure 4: Example evolutionary trajectories of fitness and background similarity. X-axis is time. Subcaption indicates respective Y-axis.

average feature vector of the prey. For evolving populations we measure the average of the average feature vector of all prey in the population.

Background Matching

Background matching is generally successful for all backgrounds in this study (see Figures 1n and 1u for particularly compelling examples), with a noteable exception and some unexpected insights. First, let us reiterate the argument initially proposed by Endler (1984). The regions of the background on which the prey are selected lead to correlations between the prey patterns and those regions of the background, because better matches generally win. In our study the random repositioning and rotation of the prey means that prey effectively have a uniform probability of being tested at each location in the image. Therefore, prey that match the average background region in the image are predicted to generally be a better fit. However, a priori it is unclear what prey patterns will appear in environments with stark differences, or natural complexity. In Figure 1g, we show one example of such a situation, where on a background of

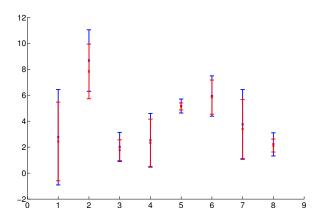

Figure 5: Background matching in prey. Y-axis indicates distance from the background, see Experiments for description of distance from background. Smaller means a better match. X-axis is the ordering of backgrounds in Figure 3.

half blue and half red the prey adopts a strategy that contains both red and blue which can be easily mutated to favor one color over the other. This is a common trend in our results; prey evolved on backgrounds with large differences at the scale of the prey favor polymorphic populations.

Interestingly, there is not a clear relationship between prey fitness and prey background matching. While this is not surprising in some senses, because fitness under competitive coevolution is a function of the competing population, where an improvement in one population masks an improvement in the competing population. It does suggest that the presence of a third-party in competitive coevolution, the environment, can non-trivially alter the coevolutionary dynamics. We discuss this in greater detail when reflecting on the representation of predator vision and prey appearance. Nevertheless, because we randomly position and orient prey, we suggest that it may be worthwhile to pursue non-random prey movement to reduce the background-averaging tendency of prey.

Coevolutionary Dynamics

On first glance, the coevolutionary dynamics in this study are fraught with the Red Queen effect. Originally presented as a dynamic describing the constant probability of extinction (van Valen, 1973), the Red Queen effect is often described as the requirement that "takes all the running you can do, to keep in the same place" (Carroll, 1871). Figure 4 shows 2 example evolutionary trajectories from the white background. In one (Figures 4a, 4c, and 4e), the prey population evolves to a near perfect solid white pattern (see the 8th image in Figure 8), and in the other (Figures 4b, 4d, and 4f), the prey population evolves first to a light grey then fixates on a yellow cross pattern for an extended period (see the 17th image in Figure 8) and ends at generation 500 with a black prey pattern as the champion. Nevertheless, by simply

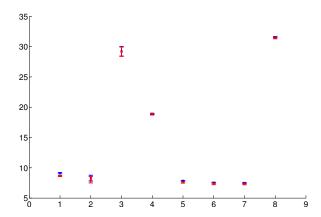

Figure 6: Prey fitness. X-axis is time. Y-axis is prey fitness. Bigger is better.

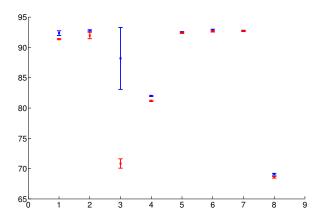

Figure 7: Predator fitness. X-axis is time. Y-axis is predator fitness. Bigger is better.

inspecting the fitness of the predators and prey it is not obvious that there has been any major change in the predatorprey interactions, certainly not to the degree that has previously been described as loss of gradient, suggesting that this dynamic is akin to relativism (Watson and Pollack, 2001).

From the set of backgrounds we used in these experiments, simple backgrounds led to the greatest degree of relativism. In particular, multiple trials with the white background resulted in evolutionary trajectories that first converged to near-white prey patterns, followed by a divergence from background similarity leading to colored patterns. We suspect that one of the reasons for this relativism was related to background discrimination ability in predators. In particular, predators make absolute decisions regarding the location of prey, where a slight change in prey hue can lead to predator misclassification. Probabilistic decisions may facilitate environmental engagement by allowing predators some degree of uncertainty in detecting prey.

Representation

Representation often has a significant impact on evolutionary dynamics by, amongst other effects, affecting the genetic distances between phenotypes and constraining the space of possible phenotypes. We utilize a genetic programming representation for prey which, by incorporating a heuristic pseudo-diffusion, is capable of producing a wide array of prey patterns. Yet these patterns are likely to have limitations that arise from both the function set used as the basis for prey programs and the instabilities that arise under diffusion (although in some systems diffusive instabilities can provide macroscopic stability, such as Turing patterns (Turing, 1952)). Furthermore, there is no interaction between prey patterns and the environment. Not only do some species exhibit active camouflage, but there are links between visible pigmentation and diet (Whitehead et al., 2012).

We suspect that the representation of predator vision is one of the more significant variables worthy of future investigation. Figure 7 suggests that predators have difficulty with multi-colored images. Prey also perform better on backgrounds with homogeneous color schemes, both in terms of fitness and background similarity, Figures 6 and 5 respectively. Due to the competitive nature of the model, it is unclear whether the bias towards homogeneous color schemes is due to the predators or the prey, but we suspect that it is due to the representation of predator vision. By considering alternative visual attention algorithms, such as those reviewed in (Borji and Itti, 2013), we expect to observe prey patterns that reflect the properties of the visual attention algorithm.

Conclusions

We have presented a model of the coevolution of predator vision and prey camouflage, where prey utilize a developmental process to form complex multicolored patterns and predators use a neurophysiologically-based model of visual attention. Prey successfully evolve to match their background, with some exceptions that are predicted to stem from randomized prey movement, and predators successfully evolve the ability to discriminate between prey and background. We observe a type of coevolutionary relativism, where competing populations remain engaged while drifting away from their environment. This type of divergence from background matching generally happens in simpler backgrounds, leading to the hypothesis that background complexity can facilitate coevolutionary engagement on background matching problems.

While other coevolutionary studies have found that pursuer-evader tasks can lead to mediocre stable states (Ficici and Pollack, 1998), we find that coevolution in our model is generally engaged and leads to effective background matching. We suggest that it is the richness of the model that facilitates engagement. However, background

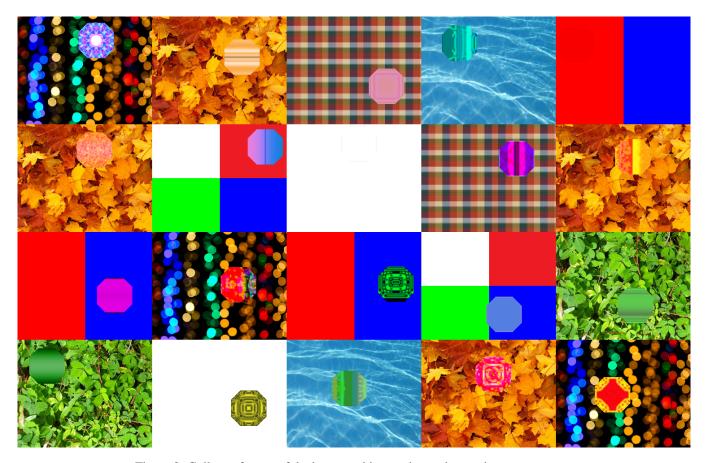

Figure 8: Collage of some of the best matching, and most interesting prey patterns

matching is not always achieved. In particular, simple environments with stark differences where only partial background matching is possible tend to favor prey that can readily mutate to match regions of the environment. This suggests that polymorphic populations may be an effective response to a highly variable background. In the case of complex backgrounds we find that predators and prey are generally more engaged, and background complexity appears to support the advance of the coevolutionary ratchet, leading to effectively camouflaged prey.

Future Work

There are many avenues for future research stemming from this work. We suggest only two examples. First, many natural predators learn over time, whereby they may become better at identifying prey during their lifetime, see (Troscianko et al., 2013). Second, in Nature, prey patterns act are signals, both to prey and to mates. It may prove interesting to consider the dynamics of mate signaling which has led to such brilliant patterns as peacocks' plumage. Along this line, we have previously discovered models and corresponding parameters capable of leading to the emergence of such costly signaling (Harrington et al., 2012).

Abstract

Gene families are sets of homologous genes formed by duplications of a single original gene. Inferring their history in terms of gene duplications, gene losses and gene mutations yields fundamental insights into the molecular basis of evolution. However, phylogenetic inference of gene family evolution faces two difficulties: (i) the delimitation of gene families based on sequence similarity, and (ii) the fact that the models of evolution used for reconstruction are tested against simulated data that are produced by the model itself. Here, we show that digital genetics, or in silico experimental evolution, can provide thought-provoking synthetic gene family data, robust to rearrangements in gene sequences and, most importantly, not biased by where and how we think natural selection should act. Using aevol, a digital genetics model with an abstract phenotype but a realistic genome structure, we analyzed the evolution of 3,512 synthetic gene families under directional selection. The turnover of gene families in evolutionary runs was such that only 21% of those families would be accessible for classical phylogenetic inference. Extinct families showed patterns different from the final, observable ones, both in terms of dynamics of gene gains and losses and in terms of gene sequence evolution. This study also reveals that gene sequence evolution, and thus evolutionary innovation, occurred not only through local mutations, but also through chromosomal rearrangements that re-assembled parts of existing genes.

Introduction

How do new genes arise? Do they evolve mainly by local mutations or domain shuffling? Which events drive them to extinction? These questions are fundamental to understand the evolutionary dynamics of living systems. Because the preservation of soft tissues is rare in fossil records, paleontology provides precious but limited knowledge of the past of the living world. The study of molecular evolution thus largely relies on the analysis of extant genes, which may or may not be a representative sample of genetic diversity throughout the evolution of life. Central in this analysis is the notion of gene family, defined as a set of homologous genes formed by duplications of a single original gene. Insights into the evolutionary dynamics at the molecular level are obtained by inferring the evolutionary history of gene gains and losses and of gene mutations in a gene family.

The usual strategy to identify gene families consists in detecting significant sequence similarities in gene or protein sequences. This method is inherently biased towards the detection of families that evolve mainly through local mutations rather than domain shuffling. As Song et al. (2008) make it clear, "multidomain sequences, especially those with promiscuous domains that occur in many contexts, are frequently excluded from genomic analyses due to the lack of a theoretical framework and practical methods for detecting multidomain homologs". Efforts are thus ongoing to develop multidomain homology identification methods (Geer et al., 2002; Enright et al., 2002; Lin et al., 2006; Song et al., 2008; Jachiet et al., 2013).

Once gene families have been identified, their evolutionary histories are inferred, using implicit or explicit models of evolution to describe the patterns of DNA base substitution and amino acid replacement (Liò and Goldman, 1998) and the patterns of gene gains and losses (Arvestad et al., 2004; Vilella et al., 2008; Akerborg et al., 2009; Rasmussen and Kellis, 2012; Boussau et al., 2013). These models of evolution make assumptions – for example, the model used by Vilella et al. (2008) assumes that gene duplications and deletions are rare events, and that duplication followed by complementary gene losses on the left and right branches of a duplication node is an unlikely scenario. Most models also assume that different gene families evolve independently, while a single duplication or deletion can actually span several genes. The scarcity of well-preserved ancient DNA samples makes it difficult to really test these hypotheses. The common practice to test a phylogenetic method is thus to simulate artificial sequences to generate benchmarks. However, these artificial sequences are usually generated with the same general model of evolution as the one used by the phylogenetic method being tested, with only minor differences (see for example Rasmussen and Kellis (2012); Boussau et al. (2013)). There is thus a form of circularity in the overall process, which could leave some important aspects of evolutionary dynamics in the dark.

To provide better benchmarks for phylogenetic inference, some simulators like EvolSimulator (Beiko and Charlebois,

2007) and ALF (Dalquen et al., 2012) have been developed independently of a particular phylogenetic inference method. For example, ALF uses classical models of evolution at the gene sequence level, but allows for the duplication or loss of several consecutive genes at once. However, both ALF and EvolSimulator simulate only one sequence per species. The action of natural selection is incorporated in the mutational process, in the sense that only mutations assumed to be neutral or beneficial are simulated. For example, mutations that would lead to the formation of a stop codon (nonsense mutations) are not allowed in ALF (Dalquen et al., 2012). In EvolSimulator, specific probabilities of duplication and loss are pre-assigned to each gene (Beiko and Charlebois, 2007). Simulators of sequence evolution are also being developed in population genetics (reviewed by Hoban et al. (2012)), to predict the molecular polymorphism expected under various demographic scenarios. All individuals of the population are simulated but the genomic architecture is usually fixed, implying that gene gains or losses are not allowed. Deleterious events are allowed but the distribution of fitness effects is predefined at each locus.

Experimental evolution of microbes is a much more direct way to study evolution. Although the time scale of these laboratory experiments is short compared to those at stakes in phylogenetic reconstruction, gene gains and losses do occur (Nilsson et al., 2005; Blount et al., 2012; Tenaillon et al., 2012; Maharjan et al., 2013; Payen et al., 2014) and frozen samples allow for a partial fossil record. In silico experimental evolution, or digital genetics (Adami, 2006), can bring a complementary perspective by providing fast synthetic genomic data, in which – in contrast to other types of simulators - the action of natural selection on genomic sequences is not predetermined by the user. In digital genetics, an abstract artificial chemistry is used to compute a phenotype from a genotype, and selection is based on the phenotype, not on the genotype. The Avida platform has already been used to test the effect of selection on phylogenetic reconstruction methods (Hagstrom et al., 2004; Hang et al., 2007). Here, we show how a digital genetics platform with a realistic genome structure can be used to directly study gene family evolution, with both local mutations and rearrangements. The exhaustive knowledge of all evolutionary events allows for the identification of gene families even when sequence similarity could be impaired by rearrangements that shuffled parts of coding sequences.

After a presentation of the model, called aevol (http://www.aevol.fr), we study the evolution of ten independent populations under directional selection, yielding 3,512 synthetic gene families. Using a new postprocessing tool designed for this purpose, we analyze the dynamics of genes within the context of those families – how and how often new genes are created, how and how often they are lost, how many and what types of mutational events occur in their

sequences. By going beyond the simple time series of gene number, we show that our usual interpretation of gene number evolution in aevol was partly wrong. Not all new genes arise by duplication-divergence. Many are also created from previously non-coding sequences, after either a local mutation or a rearrangement. We also show that there is a high turnover of gene families, many of them lasting only a few hundreds or thousands of generations. This implies that final extant genes give only a partial insight into the dynamics of gene family evolution. Moreover, our analysis reveals that rearrangements do not restrict themselves to changing gene number and gene order. They also play a significant role in gene sequence evolution, and thus in evolutionary innovation, by rearranging parts of existing genes.

Aevol: A digital genetics model

Aevol is a digital genetics model that simulates the evolution of a population of N haploid organisms through a process of variation and selection. It was designed to study the evolution of genome structure (Knibbe et al., 2007; Beslon et al., 2010; Parsons et al., 2010; Frenoy et al., 2013; Batut et al., 2013). Thus, the design of the model focuses on the realism of the genome level and of the mutational process, while the selection process simply relies on a one-dimensional curvefitting task.

Genome representation

Each artificial organism owns a chromosome whose structure is inspired by prokaryotic genomes. It is organized as a circular double-strand binary string containing a variable number of genes separated by non-coding sequences (figure 1). Genes are delimited by predefined signaling sequences indicating transcription and translation start and stop. Transcription initiates at promoters, defined in the model as sequences that differ from an (arbitrarily chosen) 22-bp consensus sequence by $d \leq 4$ mismatches. When a promoter is found, the transcription proceeds until a terminator is reached. Terminators are defined as sequences that would be able to form a stem-loop structure, as the ρ -independent bacterial terminators do. In the following experiments, terminators had the structure $abcd * * * \overline{d}\overline{c}b\overline{a}$, where $\overline{a} = 0$ if a=1, and conversely. The expression level e of an mRNA is determined according to the similarity of its promoter to the consensus: $e = 1 - \frac{d}{5}$.

Transcribed sequences (mRNAs) do not necessarily contain coding sequences. The translation initiation signal is the motif 011011****000 (Shine-Dalgarno-like sequence followed, a few base-pairs away, by a START codon). When this signal is found on a mRNA, the downstream sequence is read three bases (one codon) at a time until the termination signal, the STOP codon 001, is found on the same reading frame. Each codon lying between the initiation and termination signals is translated into an abstract "amino-acid" using an artificial genetic code (Figure 1).

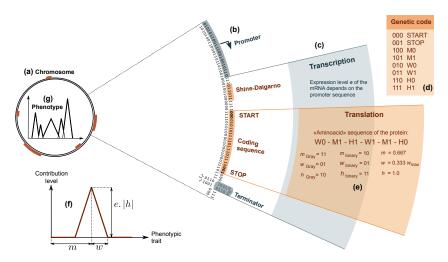

Figure 1: In the model, each organism owns a circular double-strand binary chromosome (a) along which genes are delimited by predefined signal sequences (b). Promoters and terminators mark the boundaries of RNAs (c) within which coding sequences are in turn identified between a Shine-Dalgarno-START signal and an in-frame STOP codon. Each coding sequence is then translated into a protein sequence using a predefined genetic code (d). This protein sequence is decoded as three real parameters called m, w and h (e). Proteins, phenotypes and environments are represented similarly through mathematical functions that associate a level to each abstract phenotypic trait in [0,1]. The contribution of a protein is a piecewise-linear function with a triangular shape, with position m, half-width w and height h (f). All proteins encoded in the chromosome are then combined to compute the phenotype (g), which is compared to the environmental target to compute the fitness of the individual.

Protein function and phenotype computation

In the model, we assume that there is an abstract, continuous one-dimensional space $\Omega = [0, 1]$ of phenotypic traits. Each protein contributes positively or negatively to a subset of phenotypic traits, and is modeled as a mathematical function that associates a contribution level between -1.0 and 1.0 to each phenotypic trait. For simplicity, we use piecewiselinear functions with a symmetric, triangular shape (figure 1). In this way, only three numbers are needed to characterize the contribution of a protein: The position m ($m \in \Omega$) of the triangle on the axis, its half-width w and its height h (positive or negative). The protein thus contributes to the phenotypic traits in [m-w, m+w], with a maximal contribution for the traits closest to m. Thus, various types of proteins can co-exist, from highly efficient and highly specialized ones (low w, high h) to polyvalent but poorly efficient ones (high w, low h).

In this framework, the sequence of each protein is decomposed into three interlaced binary subsequences that will in turn be decoded as the values for the $m,\,w$ and h parameters. For instance, the codon 010 (resp. 011) is translated into the single amino acid W0 (resp. W1), which means that it adds a bit 0 (resp. 1) to the Gray code of w. (The Gray code is a variant of the traditional binary code. It is widely used in evolutionary computation because it avoids the so-called Hamming cliffs: in the Gray code representation, consecutive integers are assigned bit strings that differ by only one bit.). Small mutations in the coding sequence

(point mutations, indels, possibly causing frame shifts) can change these parameters and hence change the contribution of the protein to the phenotypic traits.

Once all the proteins encoded on the genotype of the organism have been identified, their contributions are combined to get the final level for each phenotypic trait. This is done by summing the mathematical functions of all proteins and keeping the result bounded between 0 and 1.0. The resulting piecewise-linear function $f_P:\Omega\to[0,1.0]$ is called the phenotype of the organism. It indicates the level of each phenotypic trait in Ω .

Environment, adaptation and selection

In the model, fitness depends on the difference between the levels of the phenotypic traits, and target levels defined by a mathematical function $f_T:\Omega\to[0,1.0]$. This target function indicates the optimal level of each phenotypic trait in Ω and is called the environmental target, or target for short. Here, f_T was made up of three gaussian lobes with standard deviation 0.05 and maximal height 0.5, centered on x=0.2, 0.6 and 0.8 respectively. It was kept constant over evolutionary time. Adaptation was specifically measured by the gap $g=\int_{\Omega}|f_T(x)-f_P(x)|dx$ between f_P and f_T . The lower the gap, the fitter the individual. This measure penalizes both the under-realization and the over-realization of each phenotypic trait.

In the current version of Aevol, the population size is constant (here N=1,000 individuals) and the population is

entirely renewed at each generation. A probability of reproduction is assigned to each individual according to its gap and a multinomial drawing determines the actual number of offsprings each individual will have. Here, we used the so-called "fitness-proportionate" selection scheme, where the probability of reproduction of an individual with gap g was $\frac{e^{-kg}}{\sum_{i=1}^N e^{-kg_i}}.$ Here the environment was considered perfectly mixed, but a spatial grid structure where an individual competes only with its neighbors can also be used.

Mutations and rearrangements

During their replication, genomes can undergo local mutations (point mutations and small insertions or deletions of 1 to 6 bp) and chromosomal rearrangements (duplications, deletions, translocations and inversions). The breakpoints for these rearrangements are randomly chosen on the chromosome. A translocation is here defined as moving a segment to another position on the chromosome. Other versions of the platform exist that allow for plasmids, in which case translocations can move subsequences from the chromosome to the plasmids and conversely. This feature was not used here. Similarly, although lateral transfer is possible in aevol, we did not use it in these experiments, to keep the setup simple in this first study of gene family evolution. The rates of the different types of genetic modification occurs are defined per-base, per-replication.

Workflow with the software suite

The typical workflow with the aevol software suite starts with the preparation of the initial population following the initialization method chosen by the user (with a random genome or with a mix of already evolved ones, for a competition assay for example). The second step is the evolutionary run itself. Depending on the parameters, a run of 100,000 generations may take from several hours up to several days. The population size is important, but the spontaneous rates of rearrangements as well, since they influence the evolved genome size (Knibbe et al., 2007). If ancestry relationships and mutations have been recorded during the run, and if individuals were asexual, it is possible, as a third step, to extract the line of descent of the best final individual from the recorded data and to replay the evolutionary events that occurred along this successful lineage. Except for the very last mutations that were possibly still segregating in the population, the replayed mutations are those that were fixed.

Results

We let 10 populations of 1,000 haploid asexual individuals evolve independently under directional selection during 100,000 generations. The spontaneous rate of each type of mutational event was set to 10^{-5} per bp. At the beginning of a run, all organisms of the population were initialized with a same random sequence of 5,000 bp containing at least one

gene. This initial sequence was different for each population. In practice, populations started with either one or two genes. With this setup, we do not aim at mimicking the origin of life but rather the adaptation to a novel niche. Indeed, in the model, an individual without any gene on its chromosome can still replicate itself and express its genes: "Core genes" for replication, transcription, translation are assumed to be implicitly present in each individual and their evolution is not modeled. What is actually simulated is the evolution of the non-essential subset of the genome, when the population faces a new environment.

As shown by Figure 2, genome evolution on the successful lineages starts with a phase of expansion, where new genes are massively acquired, along with much non coding DNA. This excess DNA is then progressively removed from the genome, while gene acquisition slows down. This pattern was already observed in (Knibbe et al., 2007), in a similar setup. Here, we went deeper into the analysis of gene repertoire dynamics by tracking the fate of each gene, as well as the paralogy relationships between genes.

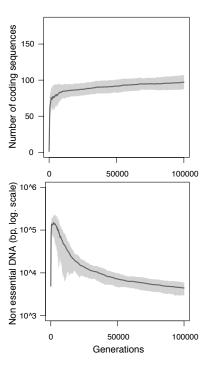

Figure 2: Evolution of genome size on the line of descent of the final best individuals. The shaded area indicates the standard deviation across repetitions. Non essential DNA is defined as DNA that can be removed without changing the phenotype. It includes intergenic DNA, but also the transcribed but untranslated regions (UTRs).

For each repetition, evolutionary events on the line of descent of the best final individual were replayed. Each gene in the initial genome was tagged and considered the root of a gene family, which was stored as a binary tree. When replay-

ing the mutational events, the fate of each gene was followed and recorded mutation after mutation. We considered in this analysis that a gene was composed of its coding sequence and of its "upstream region", defined as the sequence located between the first base pair of the first promoter of the coding sequence and the first base pair of the Shine-Dalgarno-start signal for translation initiation.

Figure 3 shows an example of a small gene family. The topology of the tree indicates the dynamics of gene duplications and losses. Because the exact timing of events is known, the branch lengths represent the real time elapsed, in number of generations. The branches are annotated with the mutational events that affected either the coding sequences or their upstream regions. These events can either be local mutations or chromosomal rearrangements. Indeed, aevol, along with the "ARN" model (Banzhaf, 2003) and potentially the model of early metabolism by Ullrich et al. (2011), is one of the few digital genetics models in which the breakpoints of chromosomal rearrangements are not constrained to intergenic regions. They operate at the sequence level rather than at the gene level and are thus blind to the genic/intergenic status of the sequences they disrupt. As a consequence, they can modify gene content and gene order, but also generate variability in gene sequences.

Number of gene families

In previous studies with aevol, which mostly relied on the time series of gene number like on Figure 2, we thought that most evolved genes ultimately descended from the initial one(s). Indeed, because simulations started with only one or two genes and because several initiation signals are necessary for a sequence to be coding, one would expect that most genes would be created by a duplication-divergence process and that each run would thus contain one or two gene families only. There were actually on average 351.2 ± 158.3 gene families per evolutionary run, contrary to what we expected. This is not an artifact due to a saturation of the phylogenetic signal, because gene family identification is here based on the exact knowledge of all events and not on sequence similarity, and is thus insensitive to such a saturation. Thus, de novo gene creation was not rare. On average, in a run, the gene families of the initialization represented only 0.4% of all families and 10.8% of the final genes. This fits with a recent analysis of proto-genes candidates in the genome of the yeast S. cerevisiae, which suggested that "de novo gene birth may be more prevalent than sporadic gene duplication" (Carvunis et al., 2012). In our synthetic dataset, 55% of de novo gene creations were due to a local mutation and around 44% were due to a chromosomal rearrangement.

The large variation across runs in the number of families stems from a bimodal distribution, with seven runs centered around 281 families (hereafter called group A) while three other runs (called group B) are centered around 632 families. This variation is due to the initial phase of genome

expansion, since on average 61% of the gene families in these three runs were extinct before generation 10,000. At the end of the runs (t=100,000 generations), on average 73.4 ± 6.2 gene families were still active in each run, meaning that they had at least one remaining gene. Thus, the families that would be accessible for classical phylogenetic inference would represent only 21% of the gene families that played a role in the evolutionary history of the evolved populations.

Size of gene families

What is usually called the family size is the number of non-extinct leaves at the time of observation. Here, the mean family size at t=100,000 was 1.36 ± 0.1 non-extinct leaves, meaning that each family had on average 1.36 sibling genes (paralogs) in the evolved genome. In real genomes, gene family size is known to follow a power-law distribution (Huynen and van Nimwegen, 1998), with a vast majority of very small gene families and a few very large families. As shown by Figure 4, the family sizes obtained here do not span enough orders of magnitude to conclude to a power-law distribution. However, in all runs, the vast majority of families had size 1, while only one or two families had a size larger than 4.

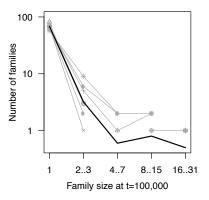

Figure 4: Distribution of gene family size at t=100,000. The different symbols correspond to the different repetitions and the black curve is the mean frequency over the ten repetitions. Following Huynen and van Nimwegen (1998), family sizes were binned exponentially and both axes are logarithmic. Missing symbols correspond to a frequency of 0.

Rates of gene duplication and loss

When taking all families of a run into account, a gene gain by duplication occurred on average every 212 generations in group A, and every 5.5 generations in group B. A gene loss occurred every 158 generations on average in group A, and every 5.4 generations in group B (63% of gene losses happened by the complete deletion of the gene, 16% were due to another chromosomal rearrangement and 21% were due to a local mutation). However, these rates of gene

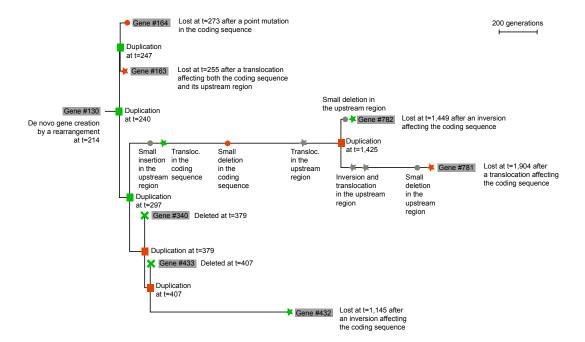

Figure 3: Example of a small gene family. This is the fourth gene family of the third run. It was born at t=214 and went to extinction at t=1,904. Squares indicate duplications, crosses indicate deletions, stars indicate inversions or translocations, and circles indicate point mutations, small insertion or small deletions. Gray events were neutral, while red events were deleterious and green events were beneficial. The topology of the tree was drawn with NJPlot (Perriere and Gouy, 1996).

gains and losses are somehow misleading because 90% of the gene duplications and gene losses occurred before generation 5,500. Hence, during the initial phase of genome expansion, the gene content is extremely dynamic. Besides, duplications and deletions generally encompass several neighboring genes, thereby creating strong correlations across families and inside different subtrees of a family. For example, in the first run, there were 604 gene duplications but they were concentrated on 85 different generations only.

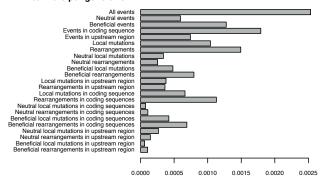

Evolutionary rates of gene sequences

On each branch of each gene family, we counted and classified the events that modified the gene sequence without killing it, and divided these counts by the branch length in number of generations. Those rates per gene per generation were averaged over all branches of all gene families of all runs to produce Figure 5A. It shows that the coding sequences underwent more changes than the upstream region. This an expected result given that (in the model) changes in the coding sequences can change the phenotypic traits to which the gene contributes, whereas changes in the promoter can just modulate the level of a gene contribution. Both local mutations and rearrangements modified gene sequences, but rearrangements were more numerous than local mutations in branches shorter than 290 generations, which represent 90% of the dataset. Thus, the mean rate of rearrangements over all branches turns up to be higher than the mean rate of local mutations. Beneficial mutations were also more frequent than neutral events, which is expected under a directional selection setting, but also depends on the fact that the artificial genetic code is not redundant. Neutral mutations can happen between the promoter and the start signal, but it is a rather small mutational target. Neutral mutations can also happen in intergenic regions, but those were not monitored here.

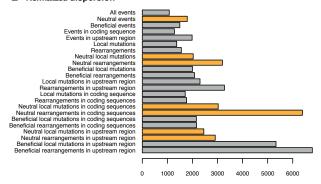

Figure 5B shows the overall normalized variation of each rate across all branches of all gene families of all runs. The indicator with the lowest normalized variation is the rate of all events that affect the gene sequence, regardless or whether they are neutral or beneficial, local mutation or rearrangement. It cannot, however, be chosen as a molecular clock, because it includes non-neutral events, whose count would be affected by the strength and type of selection. A good candidate for a molecular clock should thus both minimize its variation across branches and trees, and count neutral events only, in order to be robust to the selection regime. According to this criterion, the rate of all neutral events affecting the gene sequence, including rearrangements, would make a slightly better molecular clock than the rate of neutral local mutations only (Figure 5B, orange bars).

Analyses of gene families in real genomes of fungi, insects, and mammals have revealed a negative correlation between the age of the family and the evolutionary rate of its members (Capra et al., 2013). As shown by Figure 5C, such a negative correlation is clear in our synthetic data if all gene

A Mean rate per generation

B Normalized dispersion

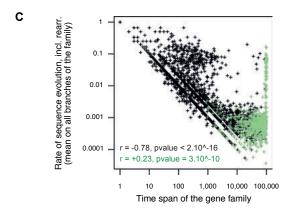

Figure 5: A. Mean evolutionary rate, per gene per generation, for each type of event (average over all branches of all gene families of all runs). B. Relative standard variation ($100 \times \text{standard deviation / mean}$) of each indicator across all branches of all gene families of all runs. Orange bars correspond to neutral indicators, candidates for a molecular clock. C. Correlation between the logarithm of family time span and the logarithm of the mean evolutionary rate in the family (black = all gene families, green = active families at t=100,000). The mean evolutionary rate of a family was computed as the average, over all its branches, of the per-generation rate of events that modify the gene without killing it. This is the indicator called "All events" in panels A and B. It includes both local mutations and chromosomal rearrangements.

families are considered (r=-0.78, p-value $< 2 \times 10^{-16}$). However, if one restricts the analysis to the observable families in the final evolved genomes, the correlation becomes positive but weaker (r=+0.23, p-value $\sim 3 \times 10^{-10}$). In the final genomes accessible to phylogenetic analyses, no trace remains from the fast evolving gene families that supported the initial (yet important) steps of the adaptation to the novel environment. Note, however, that even these final observable families evolve relatively fast and that we are actually simulating only the subset of non essential genes that confer a selective advantage in the novel environment. In contrast, in real datasets reviewed in (Capra et al., 2013), the core genes for e.g. replication and gene expression would be included. This could explain the differences in the correlation patterns between the synthetic and the real data.

Conclusion

This study of synthetic gene families revealed that, upon adaptation to a new environment, (i) there was a high turnover of gene families and extinct families showed patterns different from the final, observable ones, both in terms of dynamics of gene gains and losses and in terms of gene sequence evolution, (ii) gene sequence evolution occurred through both local mutations and chromosomal rearrangements, and (iii) incorporating chromosomal rearrangements in the evolutionary rate of gene sequences would slightly improve the accuracy of the molecular clock. Although some of the results can depend on the simplifications of the model - like the absence of redundancy of the artificial genetic code -, the study is a demonstration of how digital genetics can explore data inaccessible to classical phylogenetic methods. With refined models developed in close collaboration with phylogeneticists, digital genetics could prompt a reassessment of the biases and limitations in the studies of evolutionary dynamics of genes.

Abstract of a publication in Proceedings of the Royal Society B. 2013. 280: 20122863 (Clune et al., 2013).

A long-standing, open question in biology is how populations are capable of rapidly adapting to novel environments, a trait called evolvability. A major contributor to evolvability is the fact that many biological entities are modular, especially the many biological processes and structures that can be modeled as networks, such as metabolic pathways, gene regulation, protein interactions, and animal brains. Networks are modular if they contain highly connected clusters of nodes that are sparsely connected to nodes in other clusters (Wagner et al., 2001; Leicht and Newman, 2008). Despite its importance and decades of research, there is no agreement on why modularity evolves (Wagner et al., 2001). Intuitively, modular systems seem more adaptable, a lesson well-known to human engineers, because it is easier to rewire a modular network with functional subunits than an entangled, monolithic network (Kashtan and Alon, 2005). However, because this evolvability only provides a selective advantage over the long-term, such selection is at best indirect and may not be strong enough to explain the level of modularity in the natural world (Wagner et al., 2001).

Modularity is likely caused by multiple forces acting to various degrees in different contexts (Wagner et al., 2001), and a comprehensive understanding of the evolutionary origins of modularity involves identifying those multiple forces and their relative contributions. The leading hypothesis is that modularity mainly emerges due to rapidly changing environments that have common subproblems, but different overall problems (Kashtan and Alon, 2005) (Modularly Varying Goals: MVG). It is unknown how much natural modularity MVG can explain, however, because it unclear how many biological environments change *modularly*, and whether they change at a high enough frequency for this force to play a significant role.

We investigate an alternate hypothesis that has been suggested, but heretofore untested, which is that modularity evolves not because it conveys evolvability, but as a byproduct from selection to reduce connection costs in a network (Fig. 1, Striedter (2005)). Modularity of networks is

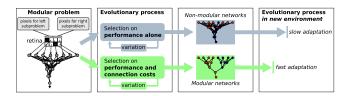

Figure 1: Main hypothesis. Evolving networks with selection for performance alone produces non-modular networks that are slow to adapt to new environments. Adding a selective pressure to minimize connection costs leads to the evolution of modular networks that quickly adapt to new environments.

measured with the Q score (Leicht and Newman, 2008).

After 25,000 generations in an unchanging environment (Fig. 2a), treatments selected to maximize performance and minimize connection costs (P&CC) produce significantly higher performing (Fig. 2c) and more modular networks (Fig. 2d) than treatments maximizing performance alone (PA) (Q = 0.42, 95%) confidence interval [0.25, 0.45] vs. $Q = 0.18[0.16, 0.19], p = 8 \times 10^{-9}$ using Matlabs Mann-Whitney-Wilcoxon rank sum test). To test whether evolved networks exhibit functional modularity corresponding to the left-right decomposition of the task, we divide networks into two modules by selecting the division that maximizes Q and color nodes in each partition differently. Left-right decomposition is visually apparent in most P&CC trials and absent in PA trials (Fig. 2e,f). Functional modularity can be quantified by identifying whether left and right inputs are in different partitions, which occurs in 56% of P&CC trials and never with PA (Fishers exact test, $p = 4 \times 10^{-11}$). Pairs of perfect sub-solution neurons – whose outputs perfectly answer the left and right subproblems – occur in 39% of P&CC trials and 0% of PA trials (Fishers exact test, $p = 3 \times 10^{-6}$).

Stress-induced variation can cause average mutation and recombination rates to be positively correlated with fitness

Daniel B. Weissman^{1,2}

¹Simons Institute for the Theory of Computing and ²California Institute for Quantitative Biosciences University of California, Berkeley, CA 94720 weissman@berkeley.edu

Introduction

Observational and experimental studies have consistently demonstrated that individuals from a wide variety of species exhibit "stress-induced variation" (SIV) - higher rates of mutation and recombination in stressful conditions (see references in Hadany and Beker (2003); Hadany and Otto (2009)). This has been seen as a form of fitness-associated variation (FAV), in which an individual's mutation and recombination rates are functions of its fitness (Beker and Hadany, 2002). Theoretical studies have shown that on a variety of biologically plausible fitness landscapes, genes coding for negative associations between fitness and mutation and recombination rates ("negative FAV") are favored by evolution (Redfield, 1988; Gessler and Xu, 2000; Hadany and Beker, 2003; Hadany and Otto, 2007, 2009; Ram and Hadany, 2012); similar effects have also been found for genetic algorithms (Srinivas and Patnaik, 1994; Beker and Hadany, 2002; Rokhlenko and Wexler, 2009), although there are counterexamples (Wexler and Rokhlenko, 2007). Thus, the empirical and theoretical results seem to be consistent: low-fitness individuals tend to have higher rates of variation, and alleles which code for this effect are expected to be favored by evolution.

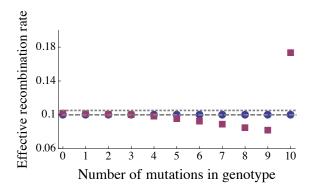

However, there is a potential issue: much of the variation in the amount of stress experienced by individuals may be caused by environmental variation rather than genetic variation, so the link between "individuals experiencing high stress" and "unfit individuals" is not completely clear. To the extent that environmental variation is completely random, with each individual experiencing small-scale fluctuations independently of every other individual, it just adds noise without disrupting the basic correlation between low genotypic fitness and high stress. But environments typically also vary in correlated ways - in particular, there are good and bad generations, where all individuals in the population feel the same decreased or increased stress, (potentially) regardless of their genotypic fitness. In fact, much of the experimental evidence for SIV comes from this kind of environmental variation, in which a population is first kept in a low-stress environment and then exposed to a stressor.

Here I show that environmental fluctuations affecting a whole population of individuals exhibiting SIV (or, more generally, population-wide changes to rates of variation) typically induce *positive* FAV – mutation and recombination rates that are positively correlated with genotypic fitness. The effect on rare genotypes with unusually high or low fitnesses is especially strong, with high-fitness genotypes having effective rates of variation many times that of low-fitness genotypes. This induced FAV can either slow or speed adaptation, depending on whether the population needs variation to occur to individuals with low fitness (to cross fitness valleys) or high fitness (to climb fitness peaks).

Model and results

Suppose that there is a population that lives in a generally mild environment but occasionally suffers stressful conditions. Under stress, an additional variation pathway is activated (e.g., a normally clonally-reproducing population undergoes sexual reproduction) or a pathway that reduces variation (e.g., kinetic proofreading) is turned off. Intuitively, during the high-variation (stressful) generations, a wide variety of genotypes are produced. These are then winnowed down by selection during the low-variation (mild) generations, so that by the time stressful conditions return, the population is composed primarily of high-fitness genotypes, which then undergo a burst of variation. This produces a bias, where higher-fitness individuals may be found more often in the high-variation generations. Note that this does not depend on the fact that increased stress was the trigger for the increase in variation; any factor that caused occasional generations with increased population-wide variation (such as increasing the mutation rate in a genetic algorithm when the rate of adaptation falls below a threshold) would have the same effect. I will stick to referring to the cause as stress, though, as it is one of the best-established mechanisms whereby this occurs.

More quantitatively, consider a period of T-1 mild generations ending with a single stressful generation. Over this time, the population as a whole experiences increased variation at an average frequency of 1/T. At what average fre-

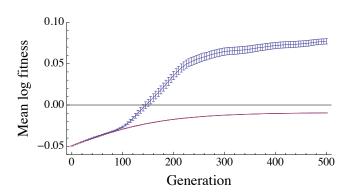

Figure 1: Comparison of populations with constant (blue) and time-varying (purple) recombination rates evolving on a 10-mutation fitness valley. (Fitness is a decreasing function of the number of mutations, except for the genotype which has all the mutations, which is the fittest). Left panel: experienced rates of recombination as a function of genotype. The dashed line shows the overall average rate, and the dotted line shows the critical rate above which the population is likely to become trapped at the lower peak (Crow and Kimura, 1965). In the variable-rate population, effective recombination rate is an increasing function of fitness. Right panel: mean log fitness of the two populations over time, with error bars showing the standard error. The population without varying recombination rates is much more successful.

quency does a particular genotype g experience it? For simplicity, assume that g is rare, has roughly constant relative fitness w_g over the T generations, and that the change in the frequency x of g is driven primarily by selection over this period. Then x(t) is simply an exponential: $x(t) \approx x(0)w_g^t$. The fraction of all g individuals alive over the T generations that experience the increased variation is $x(T)/\sum_t x(t)$, or

$$\frac{1 - w_g^{-1}}{1 - w_g^{-T}} \approx \begin{cases} 1 - w_g^{-1} & \text{for } w_g - 1 \gg 1/T \\ 1/T & \text{for } |w_g - 1| \ll 1/T \\ w_g^{T-1}(1 - w_g) & \text{for } 1 - w_g \gg 1/T. \end{cases}$$
(1)

The three different limiting cases in (1) correspond to the effect of selection on g over T generations being strongly positive, negligible, and strongly negative, respectively. Comparing them, it is easy to check that the first case has the largest effective frequency of increased variation, and the last the smallest. Note that in this limit, T does not even appear in the effective frequency of increased variation for positively-selected genotypes, suggesting that they could be disrupted even by rare stressful generations.

Effect on adaptation Perhaps the largest effect on adaptation occurs for crossing of fitness valleys (fitness landscapes in which multiple individually deleterious mutations combine to provide a fitness benefit). I show that the positive FAV induced by SIV can greatly reduce the rate of valley-crossing (Fig. 1) by increasing the effective recombination rate of the fittest genotype above the critical rate determining whether it can spread when rare. In the opposite case, a smooth landscape with many available beneficial mutations, a population with occasional bursts of recombination can adapt faster than one with a constant recombination rate (Weissman and Barton, 2012), because the induced positive FAV promotes recombination among the rare high-fitness genotypes that are driving adaptation.

Identifying Adaptations by Measuring the Trait Derivative of Fitness Extended Abstract

Drew Blount¹

¹Artificial Life Lab, Reed College, Portland, OR 97202

dblount@reed.edu

Introduction

Since Gould and Lewontin's *The Spandrels of San Marco and the Panglossian Paradigm* (1979), there has been controversy in the philosophy of biology regarding adaptationism, a research program that looks to explain evolved organisms in terms of the adaptations that comprise them. Though *Spandrels* predates the field of artificial life, its central warning should be heeded by anyone studying evolving systems, organic or artificial: it is difficult to identify adaptations.

In an evolving population where individuals have particular traits, a trait is an adaptation if it serves a function benefiting individuals' fitness, and for that reason has become prominent in the population. A much-simplified version of Gould and Lewontin's thesis is this: in general there is no way to empirically determine if a trait is an adaptation. Nonetheless, adaptationists have done so in some particular cases, generally by first conjecturing about a trait's adaptive function, and then testing other hypotheses entailed by that conjecture, confirming the adaptive premise (Dennett, 1998). It is problematic that this method can only be used when there is already a complex, plausible conjecture about a trait's adaptive function, critically limiting the set of testable traits. Further, this strategy can only conclusively confirm that a trait is an adaptation, as a negative result might only indicate that the trait has a different adaptive function than what was conjectured. There is no generalpurpose test that will tell a researcher if a trait is or is not an adaptation. This paper proposes and demonstrates such a test.

Inspired by Peter Godfrey-Smith's multi-dimensional analysis of darwinian populations (Godfrey-Smith, 2009), I analyze whether a trait is an adaptation by situating it within a three-dimensional parameter space. I measure a trait's past variability within the population, V; the trait's heritability from one generation to the next, H; and the average impact that trait has had on its host individual's reproductive fitness, the "trait-derivative of fitness," dF/dT. The necessity of considering V and H is entailed by the definition of natural selection, as I will describe. And among traits with favorable V and H values, it is those with large dF/dT values which

will, on average, become most numerous over time. Thus, there is a region of this parameter space corresponding with adaptation, and one can measure the likelihood that a trait is an adaptation by its relationship to this region.

Variability, Heritability, Differential Fitness

I will briefly describe the motivation and measurement of V, H, and dF/dT, as well as general strategies for operationalizing them. I speak only generally in this section, so that my methodology can be applied to a wide range of evolving systems.

Adaptations, by definition, only occur in populations which have previously adapted. A population can only adapt if there is variation within it, so a trait could only be an adaptation if there has previously been variation, regarding that trait, in the population of interest. To formalize this for a trait T_0 , $V(T_0)$ is a statistical measure of past variance at T_0 's locus in the evolving population.

It is clear that a trait can only be an adaptation if it is heritable – if a parent with that trait is likely to pass it on to any children. Heredity is easy to operationalize: for a trait T_0 , $H(T_0)$ is the probability that a child will have T_0 , given that its parent does.

It is often said that natural selection occurs as a combination of (at least) three things in a population: variation, heredity, and differences in reproductive fitness. This last requirement is formalized on a per-trait level in the trait-derivative: the average effect that a trait T_0 has on an individual's fitness is $\frac{dF}{dT}(T_0)$. The notation $\frac{dF}{dT}(T_0)$ is deliberately suggestive. Appro-

The notation $\frac{dF}{dT}(T_0)$ is deliberately suggestive. Appropriating the language of calculus, $\frac{dF}{dT}(T_0)$ is the expected difference in the fitness F of an organism with T_0 , if you change T_0 to $T_0 + dT$. Evaluating $\frac{dF}{dT}$ then requires operational notions of both the numerator and denominator, of fitness and trait space.

To construct or formalize a trait-space, one simply needs a measure of distance between two traits. For our purposes, this distance is closely related to H, in that $dist(T_0, T_1)$ is the probability that a parent with T_0 will have a child with T_1 . Now, the fitness of individuals within the population

must be operationalized – the exact details of this are superfluous to my argument, and different measures might be appropriate in different settings. If individual fitness can be measured or estimated well, define $F(T_0)$ as the average fitness of an individual with T_0 . $\frac{dF}{dT}(T_0)$ is then the average difference between $F(T_0)$ and $F(T_i)$, inversely weighted by $dist(T_0,T_i)$, for all traits T_i in the same trait-space as T_0 .

Identifying Adaptations in Bugs

Variation and heredity are well-understood as requirements for adaptation, and they are easily captured by standard measures of variance and probability. Because dF/dT is more novel, I will demonstrate its measurement and usefulness in an evolving population where V and H are controlled, distinguishing adaptations from non-adaped traits in Packard's Bugs artificial life model (Packard, 1989).

Bugs live in a 2d grid-world, and their 'genome' is an instruction set for where to move depending on the distribution of food within the bug's 5-cell neighborhood. Each cell either has food, or it doesn't. There are 32 possible local food maps, so there are 32 loci in a bug's genome. Genes describe movement of 1-15 steps in one of the eight cardinal directions. In my experiments, the global food map was held constant ('eaten' food does not diminish) with a centered rectangle of food covering a quarter of the world's area. In this setup, only 14 of the 32 loci in the bug genome could ever be expressed, as most 5-cell food patterns are not realized anywhere in the world map. Once each time step, every bug eats if it is standing on food, moves according to its genome and local neighborhood, and reproduces asexually if it has enough energy. Bugs lose energy when they don't eat, when they move, and when they reproduce. If a bug's energy goes below 0, it dies.

I defined the fitness of a bug at time 0 as the number of its descendants at time 1000, and the fitness of a trait as the average fitness of a bug with that trait. Genetic mutations during reproduction were locus-specific, uniformly random substitutions from trait space, so the distance between any pair of traits is equal. For this reason I did not scale by inverse distance, because that factor would be the same for each trait. $\frac{dF}{dT}(T_0)$ was then evaluated as a standardized difference between each trait's fitness and the median fitness for a trait at the same locus.

I ran 100,000 simulations with random initial populations and genomes, measuring $\frac{dF}{dT}(T_0)$ for every trait at every locus. My results illustrate the measure's usefulness, as is briefly shown in Figure 1. Bugs is a simple enough model that in many environments a human can quickly see what an 'optimal' evolutionary strategy would be - e.g., when surrounded by food, move one space (no more, because movement is expensive) in any cardinal direction. Obviously beneficial traits like these had by far the highest measured values of $\frac{dF}{dT}(T_0)$.

Genetic Locus	Outlier of	dF/dT	Move Rule
(local food map)	interest	,	(Phenotype)
	$\min \frac{dF}{dT}$	-0.9	15 NW
	$\max \frac{dF}{dT}$	328.6	1 S
	$\min \frac{dF}{dT}$	-2.8	13 NE
	$\max \frac{dF}{dT}$	8.9	14 S
	$\min \frac{dF}{dT}$	-1.3	1 W
	$\max \frac{dF}{dT}$	1.47	5 E

Figure 1: dF/dT was measured for every trait at every locus in the bug genome. Shown are the extreme dF/dT values at a very active, slightly active, and inactive locus, top to bottom. Notice the difference in magnitudes of maxima. Also note that for the active loci, the highlighted traits correspond with extremely good and bad strategies, given the environment's food distribution.

Conclusion

In the study of artificial life, as in biology, it is useful to discern which traits are adaptations. I have introduced the first general-purpose empirical test to make this classification. In this test, a trait's historical variability V, heritability H, and differential effect on fitness dF/dT are measured. Measuring these three values for a trait tells us if it is an adaptation—there is a boundary surface in this three-dimensional parameter space between adaptations and other types of traits. It will be fruitful to explore this boundary surface by plotting known adaptations against known non-adaptations, as I have shown in the ALife model Bugs. The results from Bugs are encouraging: at least in this simple system, my test is practicable and effective at identifying adaptations.

Abstract

Evolvability is the capacity of a genotype to rapidly adjust to certain types of environmental challenges or opportunities. This capacity, documented in nature, reflects foresight enabled by the capacity of evolution to capture and represent regularities not only in extant environments, but in the ways in which the environments tend to change. Here we posit that evolvability substantially benefits from the hierarchical representations afforded by Gene Regulatory Networks (GRNs). We present an extension of standard Genetic Algorithms (GAs) and demonstrate its capacity to learn a genotype phylogeny able to express rapid phenotypic shifts in the context of an oscillating environment.

Introduction

GAs are methods well-suited for search and optimisation in non-linear and high-dimensional problems. Convergence to near-optimal solutions is often perceived as the goal for GAs. However, overspecialisation can produce fragile solutions. In nature, selection also sustains *evolvability*, the capacity to change. The simplest form of evolvability is simply variation—the rate of evolution is determined by the amount of variation in a population (Fisher, 1930; Price, 1972; Reisinger and Miikkulainen, 2006; Hu and Banzhaf, 2010). More specialised evolvability can be achieved via hierarchical representations, for example single-gene control of beak length in Darwin's finches (Campàs et al., 2010). Evolvability allows rapid adaptation to regular changes in the environment, whilst also preventing premature convergence to local optima.

Here we present a system for discovering highly-evolvable genomes by exploiting GRNs (van Dijk et al., 2012; Payne et al., 2013). GRNs are already known to produce robustness via evolvability (Aldana et al., 2007a; Crombach and Hogeweg, 2008). The many-to-one mapping mechanism of genotype to phenotype implicit in GRNs enables genes to buffer against and even exploit likely variations in the genome. In addition, such a dual learning system—coupled plasticity—is known to accelerate evolution in the right contexts (Hinton and Nowlan, 1987; Kashtan et al., 2007; Borenstein and Krakauer, 2008).

Hinton and Nowlan (1987) focus on the interaction between evolution and learning, showing that coupled plasticity can solve a problem that is extremely difficult for an evolutionary process on its own. Our aim and approach here are similar, but our mechanism and outcome are novel. We explore how the robustness of GRNs can improve the evolvability of GAs by exploiting GRNs for learning structure required for quick adaptations to environmental change. This paper contributes: 1) a biologically-motivated GRN model and associated understanding of its dynamics, and 2) a demonstration of learning a quick and robust response to a changing environment—in other words, improved evolvability.

Related Work

We introduce some fundamental biological aspects of GRN, and discuss several GAs that have similar goals and properties

Gene Regulatory Networks

GRNs control the expression of genes for providing phenotypic traits in living organisms. They play a central role in cells and govern cell differentiation, metabolism, the cell cycle, and signal transduction (Karlebach and Shamir, 2008). A GRN contains a network of genes (regions of D-NA sequences) with interaction mechanisms for controlling gene expression. Epigenetic factors control the regulation of gene expression in the network without changing the genes. Shifts in gene regulation provide plasticity where organisms can adapt to environmental change. The presence of genes in the network and interactions between genes creates this plasticity.

There are a number of prior studies exploring both theoretical and practical aspects of GRNs from a biological perspective. Aldana et al. (2007b) studied the robustness and evolvability of the attractor landscape of GRNs under the process of gene duplication followed by divergence. Balleza et al. (2008) showed the criticality coupled in GRNs can generate the great diversity of dynamically robust living forms. Crombach and Hogeweg (2008) demonstrated that long-term evolution of complex GRNs in a changing environment can increase the efficiency of generating beneficial mutations.

Network Structures in Evolutionary Algorithms

Graph structures are common in Evolutionary Algorithms (EAs), such as undirected acyclic graphs (trees) in genetic programming (Koza, 1989) and cyclic graphs in evolutionary programming (Fogel, 1962). Genetic programming and grammatical evolution (Ryan et al., 1998) contain redundant genes in the chromosome, allowing some unexpressed genetic variation to be carried through generations. This redundancy can act like a memory system to enhance evolvability in dynamic environments. For example, Goldberg and Smith (1987) explored a diploid GA (with dominance operators) where a gene contains two alleles. A diploid GA was shown to adapt quicker to environmental change than a haploid (one allele per gene) GA. As well as redundancy, indirect encodings are beneficial for improving evolvability and they more closely represent the robustness and complexity found in nature (Reisinger and Miikkulainen, 2006; Reisinger et al., 2005).

Until recently, EAs had not incorporated the epigentics of GRN (Hu and Banzhaf, 2010). Lopes and Costa (2013a,b) use a model of GRN, which they refer to as an artificial regulatory network (ARN), to exploit epigenetics in genetic programming and grammatical evolution for the inverted pendulum problem, drawing artificial art, and the artificial ants problem (Sante Fe Trail problem). GRN in an EA has also been applied to financial trading (Nicolau et al., 2012). None of these GRN-based approaches to machine learning with EAs specifically address evolvability and the use of GRNs for handling environmental change. However, several authors have suggested there may be benefits to the approach (Hu and Banzhaf, 2010; Lopes and Costa, 2013a).

Model: GRN with Sexual Reproduction

The GRN with Sexual Reproduction model extends the standard GA with a GRN representation and associated reproduction and mutation operations which are different from the standard GA (see more details below). A simple model GRN provides a mechanism for improving evolvability: The interaction network is a multi-layer learning system. During the evolution process we used sexual rather than asexual reproduction in GRN because in tests it achieved better performance ¹.

GRN with Sexual Reproduction models the evolutionary process in the following steps, which are detailed in pseudocode in Algorithm 1. A large number of gene regulatory networks with a certain level of connectivity c are generated randomly; of these stable networks are selected. Then, all

the stable networks are re-selected based on their fitness. A certain number of networks are mutated according to the given mutation rate, P_m . Finally, all networks in the population undergo free combination² (Azevedo et al., 2006) during sexual reproduction.

Artificial Gene Regulatory Network

The GRN model from Wagner (1996); Siegal and Bergman (2002); Azevedo et al. (2006) is well established and provides the basic model of gene interactions required to demonstrate its capacity to learn an evolvable genotype.

For each individual in a finite population M, an $N_{qene} \times$ N_{gene} matrix W is an artificial gene network that contains the regulatory interactions among N_{gene} genes. An example is given in Figure 1A. Each element $w_{i,j}$ (i,j) $1, 2, \ldots, N_{qene}$) represents the regulatory effect on the expression of gene i of the product of gene j (see Figure 1B). The connectivity parameter c determines the proportion of non-zero elements in the network W. Through gene interactions, the regulatory effect acts on each gene expression pattern (in network W) are denoted by a state vector $\mathbf{S}(t) = (s_1(t), s_2(t), \dots, s_{N_{gene}}(t))$ where $s_i(t)$ represents the expression pattern of gene i at time t. Each value of expression state $s_i(t)$ is within the interval [-1,1] that expresses complete repression (-1) and complete activation (+1). For a given gene regulatory network W, the dynamics of S for each gene i is modelled by

$$s_i(t+1) = f\left(\sum_{j=1}^N w_{ij} s_j(t)\right),\tag{1}$$

where f(x) is a sigmoidal function. In this paper, we defined $f(x) = 2/(1+e^{-ax})-1$, where a is a free parameter determining the rate of change from complete repression to complete activation. When a is large enough, for example $a=1,000,\,f(x)$ is degenerated similarly as a sign function where f(x)=-1 for $x<0,\,f(x)=+1$ for x>0 and f(0)=0.

In all simulations, we defined the network developmental stability as the progression from an initial expression state to an equilibrium expression state (reaching a fixed pattern) by iterating Equation (1) within a fixed number of times, devT. A simple example of iterating Equation (1) is given in Figure 1C. If a given network W can achieve developmental stability, it is termed as viable or stable network, otherwise it is labelled unviable or unstable. We determined that an equilibrium expression state can be reached when the following equation is met

$$\frac{1}{\tau} \sum_{\theta=t-\tau}^{t} D\left(\mathbf{S}(\theta), \overline{\mathbf{S}}(t)\right) \le 10^{-4},\tag{2}$$

¹We did the same simulation with asexual GRN model, and found it was evolved very slow (the fitness was only improved a little during each shifting cycle) compared with sexual GRN model.

²For more details of implementation of free combination see the cited paper.

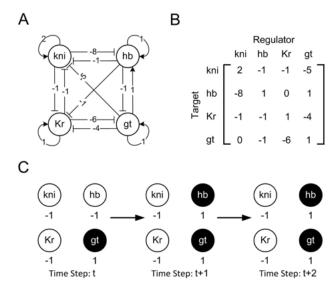

Figure 1: Example of gene regulatory network model in the gap gene system of Drosophila melanogaster, reproduced from Azevedo et al. (2006). (A), Network representation of the regulatory iteration between four gap genes (giant (gt), hunchback (hb), knirps (kni), Krüppel (Kr)) (Crawley, 2002). Gene activations and repressions are denoted by arrows and bars, respectively. Numbers on each directional edge indicate the strength (weight) of interaction between the two linked genes (Jaeger et al., 2004). (B), Interaction matrix (W) represents the network in A. Each element in row i and column j, i.e., w_{ij} , represents the regulatory effect on the expression of gene i of the product of gene j. (C), Graphical representation of the gene expression states of each gap gene over three successive time steps. We use -1 (unfilled circle) to denote the complete repression state if $s_i(t) \leq 0$, and 1 (filled circle) to represent complete activation state if $s_i(t) > 0$. Therefore, the state vectors [kni, hb, Kr, qt] of four gap genes at time t, t+1, and t+2 are S(t)=(-1,-1,-1,1), S(t+1)=(-1, 1, -1, 1), and S(t + 2) = (-1, 1, -1, 1), respectively. Successive iterations beyond the t+2 step do not change the gene expression pattern, which is the hallmark of a stable equilibrium.

where $D(\mathbf{S}, \overline{\mathbf{S}}) = \sum_{i=1}^{N_{gene}} \left(s_i - s'_i\right) / 4N_{gene}$ measures the difference between the gene expression pattern \mathbf{S} and $\overline{\mathbf{S}}$, and $\overline{\mathbf{S}}$ is the average of the gene expression levels over the time interval $[t - \tau, t - \tau + 1, \dots, t]$. Unless otherwise specified, we used devT = 100, $\tau = 10$, and a = 2 in all simulations.

Initialisation

Each individual in population M was generated with a gene regulatory network W associated with an expression state vector $\mathbf{S}(0)$. The network was generated by randomly filling

W with $c \cdot N_{gene}^2$ non-zero elements $w_{i,j} \sim N(0,1)$. The associated initial expression state $\mathbf{S}(0)$ was randomly setting each $s_i(0)$ to -1 or 1.

Selection

Competitive selection occurs using roulette-wheel selection. Survivors are placed in a new population.

Mutation

Offspring are generated by picking an individual at random from the population and placing in the new population. Then, in the selected network, each non-zero entry in the W interaction matrix was replaced by $w'_{i,j} \sim N(0,1)$ with probability P_m . Note that mutations should be viewed as operating on the $c \cdot N_{gene}^2$ cis-regulatory elements, not the coding sequences of the N_{gene} genes themselves. In other words, the mutation operation cannot change the topology of the original network W. Only offspring that are capable of producing a stable gene expression pattern survive. This process is repeated until the same amount of developmentally stable networks are produced.

Sexual Reproduction

Offspring are generated by picking two individuals at random from the population. Then the chosen two networks undergo sexual reproduction, selecting rows of the W matrices from each parent with equal probability. This process is similar to free recombination between units formed by each gene and its cis-regulatory elements, but with no recombination within regulatory regions.

Phenotype and Fitness

The fitness of an individual is determined by its phenotype. Here this is the subset of its genotype that is expressed. While in Nature the GRN might determine any number of traits to be expressed, here the fitness function considers only a fixed number (N_{PhT}) of the most upregulated genes. Level of regulation is determined by the GRN as per Equation 1. For more details of implementation of above operations please refer to Algorithm 1.

Experiments

Approach

As previously reviewed, evolvability is facilitated by redundant encoding which maintains variation, allowing quick changes to be made between good solutions. Here we have not only dual chromosomal structure, but gene activation driven by the GRN. Neither redundancy nor evolvability more generally necessarily improve EAs—in some cases these can slow evolution (Reisinger and Miikkulainen, 2006). As with all evolution and learning more generally, a gradient is required.

We compared the GRN with Sexual Reproduction model with a standard GA (Holland, 1975) to assess its capability

and potential benefits for machine learning in environments that change. Here, we apply selective pressure for evolvability by changing the fitness function. We create a modified version of MaxOnes, called MaxABs. This assigns fitness according to the proportion of expressed genes that conform to the current environmental expectation, which switches between A and B after a set number of generations, which is defined by the parameter G_{shift} (see also Kashtan and Alon, 2005). For example, the first 20 generation's fitness is $\frac{number\ of\ As}{number\ of\ As+Bs}$, in the phenotype, the next 20 is $\frac{number\ of\ As}{number\ of\ As+Bs}$, the next 20 reverts to $\frac{number\ of\ As}{number\ of\ As+Bs}$, and so on. Note that for fitness, we only count As and Bs that are in the expressed genes.

Three experiments were conducted with mostly the same model parameters, but different chosen N_{qene} , N_{PhT} and

time lags (G_{shift}) between environmental changes.

Parameters

Unless specified, the mutation rate is fixed at $P_m=0.001$ for the GA and GRN with Sexual Reproduction model in all simulations. For the GA, the recombination probability P_r is fixed to be 0.7, and for the GRN with Sexual Reproduction model, free recombination is used. Network connectivity c was set to small (details below) for all runs of the GRN with Sexual Reproduction model. This is because theory shows that selection for robustness will favor more sparsely connected and minimally complex networks (Leclerc, 2008). Roulette wheel selection is used in both approaches. In all experiments, the population size was $Pop_{size}=50$. Unless specified, 500 independent runs were conducted.

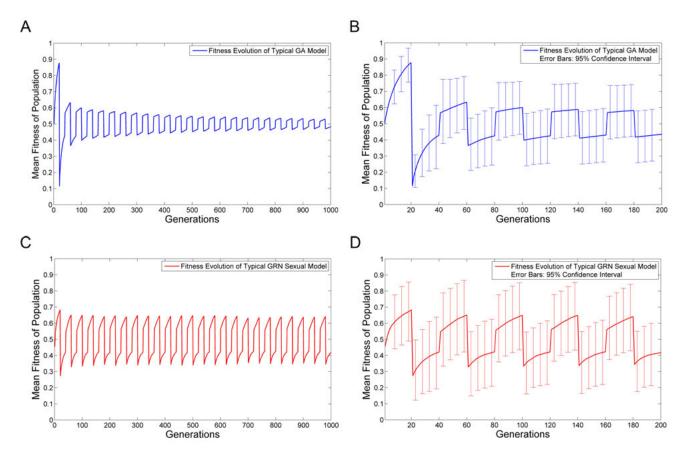

Figure 2: Evolution of both algorithms with small time gaps $(G_{shift}=20)$ between environmental change for typical GA model (A) and typical GRN with Sexual Reproduction model (C). The first 200 generations of GA and GRN with Sexual Reproduction model are shown in (B) and (D), respectively. Error bars indicate 95% confidence interval based on 500 independent runs.

Small Time Gaps Between Environmental Change

The fitness function was configured to switch between As and Bs every 20 generations to assess evolvability in frequently changing environments. The algorithms were terminated at 1,000 generations, the number of genes was $N_{gene}=20$, of which $N_{PhT}=10$ occur in the phenotype, and network connectivity was c=0.25. The mean fitness values in each population for the GA and GRN with Sexual Reproduction model are shown in Figure 2. Two observations are made.

The first observation is that the mean fitness increases to about 0.9 (for MaxAs) in the GA model, whereas it increases to about 0.7 in the GRN with Sexual Reproduction model. But for both models, the fitness does not reach the same magnitude of mean fitness in the subsequent MaxAs targets.

The second observation is that after the first two changes in fitness function (one for MaxAs and one for MaxBs) the GRN with Sexual Reproduction model has higher mean fitness than the GA. This is especially clear when the GA evolves in more cycles. The GA's mean fitness is less and

this suggests the GA is less evolvable than the GRN when switching between MaxAs and MaxBs.

Note that the goal of optimisation is to maximise the fitness value which is switching between MaxAs and MaxBs. Shifting from one peak with relatively high fitness to an even higher fitness peak is usually much more difficult than shifting from a low fitness stage to a higher fitness peak. In Figure 2, it seems that the GRN with Sexual Reproduction model has higher fitness for MaxAs and worse fitness for MaxBs. The reason is because their starting points are different. In fact, the relative increase of fitness is the same between MaxAs and MaxBs. In our simulation, we did observe that if we would give MaxBs enough time, then fitness of MaxBs can be increased to be the same level as the fitness of MaxAs.

Large Time Gaps Between Environmental Change

Based on the observation from the results produced from a small time gap, the fitness function was increased to switch between MaxAs and MaxBs every 200 generations

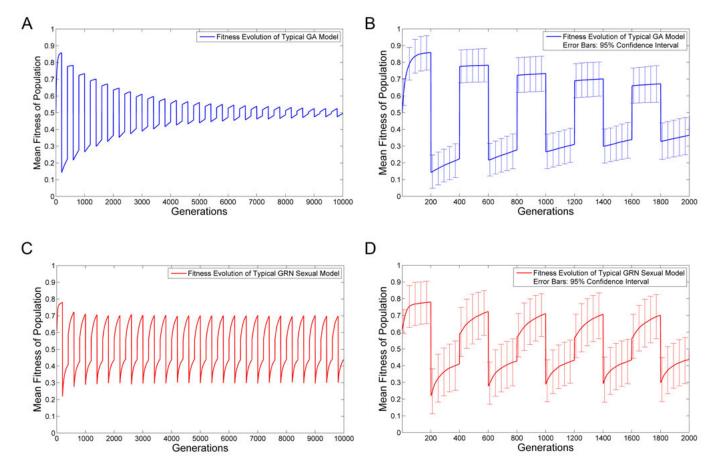

Figure 3: Evolution of both algorithms with large time gaps ($G_{shift}=200$) between environmental change for typical GA model (A) and typical GRN with Sexual Reproduction model (C). The first 2,000 generations of GA and GRN with Sexual Reproduction model are shown in (B) and (D), respectively. Error bars indicate 95% confidence interval based on 500 independent runs.

and the algorithms ran for longer by terminating at 10,000 generations. We set the phenotype to be the entire genotype, $N_{gene} = N_{PhT} = 30$, and network connectivity c = 0.05. The purpose is to assess evolvability in less frequently changing environments, but also to check the impact of redundant encoding (see experiment 3 below).

The mean fitness values in each population for the GA and GRN with Sexual Reproduction model are shown in Figure 3. Four observations are made.

The first observation is that the mean fitness of both algorithms is largest in the first time gap, which is the same for both short and long time gaps.

The second observation is that the GA has a higher mean fitness in the first time gap than the GRN with Sexual Reproduction model. This suggests the GA performs better for MaxABs *without* environmental change and the GRN with Sexual Reproduction model performs worse (perhaps learns more slowly) in a static environment.

The third observation is that the GA's mean fitness di-

minishes gradually as the fitness function is switched (Figure 3A). However, the GRN with Sexual Reproduction model achieves the same mean fitness every time the fitness function is switched (Figure 3C). This further supports that the GA is less evolvable than the GRN with Sexual Reproduction model, because the GA is less able to adapt to a regular environmental change.

The fourth observation is that the GRN with Sexual Reproduction model has steeper gradients of mean fitness in each time gap (Figure 3D). This suggests the GRN with Sexual Reproduction model is more evolvable than the GA.

Advantages of Redundant Mapping in GRN

In the first experiment, there was a redundant mapping in the GRN, but we purposely set no redundant mapping in GRN in the second experiment. Both experiments show that the GRN with Sexual Reproduction model is capable of evolving in a changing environment. However, we didn't clearly observe any advantage of redundant mapping embedded in

the GRN in short time lags. Therefore, we conducted an additional experiment to further test whether there would be a benefit of many-to-one mapping of genotype to phenotype in GRN in longer time lags.

In this experiment, the fitness function switched between MaxAs and MaxBs every 200 generations and the algorithm terminated at 5,000 generations. We set the number of genes in the genotype to $N_{gene}=20$, of which $N_{PhT}=10$ are expressed in the phenotype for selection, and network connectivity c=0.25. The result is shown in Figure 4 based on 250 independent runs. Compared to the previous experiments, two observations are made.

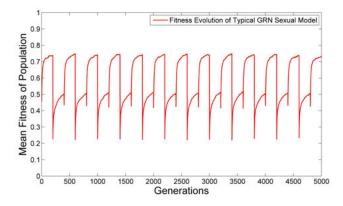

Figure 4: Evolution of typical GRN with Sexual Reproduction model with redundant mapping and large time gaps $(G_{shift}=200)$ between environmental change.

The first observation is that the GRN with Sexual Reproduction model fully recovers from the change in environment: the mean fitness in subsequent cycles can be restored to almost the same magnitude as the first cycle.

The second observation is that the GRN with Sexual Reproduction model can adapt to new environment much faster compared to Figure 2. This is particular clear when the environment switched from MaxBs to MaxAs. We further tracked how many generations would the GRN with Sexual Reproduction model be able to reach the set value of fitness³ in the first and the last cycle of MaxAs and MaxBs during the evolution. We found the GRN with Sexual Reproduction model took 150 and 103 generations on average to reach the set fitness values for MaxAs and MaxBs, respectively, in the first cycle, where as it only took 119 and 48 generations on average to reach the set fitness values in the last cycle. This is clear evidence of evolvability.

Summary & Discussion

In this paper, we show that the typical GRN with Sexual Reproduction model is capable of evolving evolvability. and thus evolving faster than the typical GA model in a changing environment. We designed two situations to mimic the changing environment, forcing the population in GA and GRN with Sexual Reproduction model to evolve in shorter and longer time lags. We found that the evolvability of the GA model decreases as it tends towards a mean value for both environments. In contrast, the GRN with Sexual Reproduction model is able to continuously evolve in both cases, retaining peak performance. In addition, although the GA model converges faster than the GRN with Sexual Reproduction model, this convergence results in a lack of diversity and evolvability. This result shows the potential advantage of using hierarchical structures such as the GRN with Sexual Reproduction model to solve problems of dynamic environments that nevertheless vary in structured ways—a task that less-structured GAs are not equipped to address.

Abstract

The evolvability of a system is the ability to generate heritable, novel and non-lethal phenotypes, from random genetic mutations. However, most evolutionary computation studies estimate evolvability either as, (i) the proportion of mutations beneficial to an individual's performance, irrespective of the phenotypic diversity of the mutants, or (ii) the range and diverseness of mutated phenotypes, without taking into account the viability of the genetic change. This paper reports a novel approach to measure the evolvability provided by an encoding, by characterizing both the quality of the mutations and the quantity of phenotypic variation. We evolved controllers for hexapod robot locomotion using a parameterized direct encoding, and the generative encoding of artificial neural networks (similar to HyperNEAT) and single-unit pattern generators (SUPGs). Our results reveal that the performance of an encoding is not always a good assessment of evolvability. Although both the generative encodings evaluated had individuals with high performance gaits, there were apparent differences in their measured evolvability. A direct and predictive relationship is indicated between our measure of evolvability, and the number of generators required by amputated individuals to recover an effective gait.

Introduction

The capacity of a population to rapidly adapt to novel environments, called evolvability, is critical in the evolutionary processes of natural organisms and artificial systems (Hu and Banzhaf, 2010). In the natural world, the high evolvability of biological systems is hypothesized to be responsible for the rich diversity of the millions of species creatively adapting to diverse niches, all arising from a combination of random mutations and natural selection (Pavlicev and Wagner, 2012). Evolvability is also of interest in evolutionary computation (EC), wherein highly evolvable solutions are considered to optimize faster and achieve a greater performance than non-evolvable solutions (e.g., Cheney et al. (2013)), and may be capable of of generalizing previously learned information and adapting it to new environments (e.g., Reisinger et al. (2005); Clune et al. (2013)), desirable characteristics from an engineering perspective.

The developmental mechanisms translating genetic change into phenotypic change, that is the genotypephenotype map, is commonly understood to play a key role in the evolvability of evolutionary systems (Kirschner and Gerhart, 1998; Wagner and Altenberg, 1996). Mappings facilitating evolvability, confer on the individual a robustness to lethal mutations, and exhibit a modular architecture wherein genes preferably only affect traits with the same function (Pavlicev and Wagner, 2012). Inspired by the evolvability of biological systems, researchers in EC have abstracted the underlying developmental processes, to formulate generative genotype-phenotype maps for artificial systems (e.g., Stanley (2007)). The resultant generative encodings frequently outperform traditional direct encodings for various application problems such as, designing 3D objects (e.g., Hornby (2005)), game playing (e.g., Reisinger and Miikkulainen (2007); Gauci and Stanley (2010)), pattern matching (e.g., Clune et al. (2011)), and robot locomotion (e.g., Hornby and Pollack (2002); Seys and Beer (2007)). Furthermore, the higher evolvability provided by generative encodings is often considered as the reason for the observed differences in performance, consequent to their capability to reuse parts of the genotype to affect different phenotypes, scale well to large phenotypic spaces, and generate modular architectures (Stanley and Miikkulainen, 2003).

In the field of EC, there are two main approaches to estimate the evolvability of artificial developmental systems. Most studies estimate evolvability either as, (i) the proportion of genetic mutations that are beneficial to an individual, irrespective of the phenotypic novelty of the resultant offspring (e.g., Hornby et al. (2003); Reisinger and Miikkulainen (2007)), or as (ii) the range and diversity of the phenotypic variants resulting from genetic change (Lehman and Stanley, 2011; Reisinger et al., 2005; Lehman and Stanley, 2013), usually without considering the deleteriousness of the change. Importantly, both these estimates when considered alone do not discount for mutations that, (i) generate very diverse phenotypes but prove lethal to an organism, and (ii) result in minor improvements to a phenotype, but are unable to generate novelty. According to the theory of facilitated variation (Gerhart and Kirschner, 2007), the capacity of an individual to evolve is a function of its ability to curtail lethal mutations, and simultaneously to decrease the number of mutations necessary to evolve diverse or novel phenotypes.

In this study we present a novel approach to visualize evolvability provided by direct and generative encodings, featuring both the quality and quantity of phenotypic variation consequent to genetic change, for hexapod robot locomotion. Evolvability is analyzed for a parametrized direct encoding, and the generative encoding of artificial neural networks (similar to HyperNEAT, Stanley et al. (2009)) and single-unit pattern generators (Morse et al., 2013), in three independent experiments. The significance of our measure of evolvability is analyzed by the ability of the robot to adapt to previously unencountered changes in its morphology.

Measuring evolvability

The evolvability provided by the direct and generative encodings is measured by computing the effect of genetic mutations on, (i) the viability of the mutated individual, and (ii) the diversity of phenotypes generated. The two resultant effects are treated separately instead of being combined into a single quantitative measure of evolvability, to consider the trade-offs between them in their individual influence on evolvability.

Feature 1: Deleteriousness of mutations. The first feature in our measure of evolvability is computed as the proportion decrement in the fitness of a mutated individual.

For an individual i and the mutant i', we have,

$$f_1 = (F_i' - F_i)/F_i (1)$$

where F_i and F'_i , are the fitness values before and after the application of a random genetic mutation, respectively.

The feature f_1 reflects the phenotype quality following beneficial ($f_1 > 0$), neutral ($f_1 \approx 0$), and deleterious ($f_1 < 0$) 0) genetic change.

Feature 2: Diversity of phenotypes. The second feature in our measure of evolvability is quantified as the difference in the phenotype, resulting from genetic mutation. There are many available diversity metrics to measure behavioral differences, ranging from the classical euclidean distance, to correlation coefficients, and various information theoretic measures (reviewed in Mouret and Doncieux (2012)). The mutual information metric, in comparison with other measures such as correlation, provides a more general criterion to investigate statistical dependences between behaviors, and is applicable to numerical and symbolic phenotypic representations.

We compute the phenotype diversity as the normalized mutual information (Cover and Thomas, 1991) between behaviors of an individual, before and after its genome is mutated. Assuming that the behavior of an individual i can be represented as a discrete vector B_i (details in Mouret and Doncieux (2012)), for the behaviors B_i and B'_i , of individual i and mutant i', we have:

$$H(B_i) = -\sum_{b_i \in B_i} p(b_i) \log p(b_i)$$
 (2a)

$$H(B_i) = -\sum_{b_i \in B_i} p(b_i) \log p(b_i)$$
(2a)

$$H(B_i, B'_i) = -\sum_{b_i \in B_i} \sum_{b'_i \in B'_i} p(b_i, b'_i) \log p(b_i, b'_i)$$
(2b)

$$f_2 = 1 - \frac{H(B_i) + H(B_i') - H(B_i, B_i')}{max(H(B_i), H(B_i')}$$
(2c)

where $H(B_i)$ is the entropy of the behavior B_i comprising the individual states b_i with probability $p(b_i)$, $H(B_i, B'_i)$ is the joint entropy between behaviors B_i and B'_i with joint probability density function $p(b_i, b'_i)$, and f_2 denotes the inverse of the normalized mutual information between the two behaviors.

The feature f_2 in our measure of evolvability represents the quantity of phenotypic variation following genetic change, and is indicative of the ability of the evolutionary system to produce novel phenotypes.

Hexapod locomotion problem

The evolution of locomotion gaits for multilegged robots is a classical problem in EC, addressed in many prior studies utilizing both direct and generative encodings (e.g., Liu and Iba (2004); Clune et al. (2011); Valsalam and Miikkulainen (2008)). In the large majority of these studies, the performance of evolved individuals is analyzed solely by the walking speed of the robot and the required number of generations of evolution. The rate of evolution and evolved performance has also been linked to evolvability provided by the encoding scheme, wherein controllers achieving a higher task fitness and requiring fewer generations to evolve are considered more evolvable (e.g., see Hornby et al. (2003); Komosiński and Rotaru-Varga (2001)). While these approaches provide interesting insights on the characteristic of the underlying genotype-to-phenotype mapping, they largely ignore its capabilities to generate viable phenotypic variations (diverse gaits in case of legged robots). However, the diversity of evolved walking gaits is important for the legged robot to recover rapidly from faults such as, the loss of one or more limbs, or motor malfunctions (Koos et al., 2013), and for the robot to adapt to previously unencountered environmental changes. Furthermore, an efficient recovery is particular relevant for hexapedal legged robots, wherein the probability of component failure is high, consequent to the large number of moving parts.

Hexapod platform details: The hexapod robot is simulated on a flat, horizontal surface (Fig. 1a), with the Open Dynamics Engine¹ (ODE) physics simulator. The robot has 18 Degrees of Freedom (DOF), 3 for each leg (Fig. 1b), and each DOF is actuated by a single servo. The first servo on each leg (s₁) actuates the horizontal orientation of the leg within range $[-\pi/8, \pi/8]$ radians. The second (s₂) and third

¹http://www.ode.org

(s₃) servos control the leg elevation and extension, respectively, each within the range of $[-\pi/4, \pi/4]$ radians.

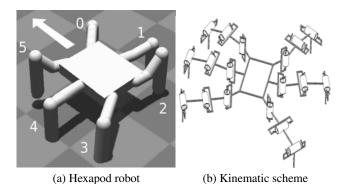

Figure 1: (a) Snapshot of an 18-DOF simulated hexapod robot walking on a horizontal surface, with contacts simulated. (b) Kinematic scheme of the robot, with cylinders representing actuated pivot joints. The three servos on each leg, s_1 , s_2 and s_3 , are labeled in increasing order of distance to robot torso.

Angular positions are sent to the 18 servos once every 15 ms. Furthermore, in order to maintain the last subsegment of each leg vertical (for enhanced stability), the control signal for the third servo (s_3) is always in antiphase to that of the second servo (s_2) . Consequently, the robot is reduced to a 12 DOF system, despite being actuated by 18 motors.

Hexapod gait representation: The phenotypic diversity in our measurement of evolvability corresponds to the intergait diversity in the hexapod robot locomotion problem. For this measurement, a hexapod gait is represented using a gait diagram (Kajita and Espiau, 2008, p. 379), comprising a binary matrix C of leg-surface contacts:

$$C_{tl} = \begin{cases} 1 & \text{if leg } i \text{ makes surface contact at time-step } t, \\ 0 & \text{otherwise.} \end{cases}$$

where $t \in \{0...T\}$, the gait is evaluated for T time-steps, and the hexapod legs $l \in \{0...5\}$.

The hexapod gait for an individual i is represented by binary vector B_i , comprising the contacts in C concatenated in row-major order, $B_i = [C_{00}, C_{10} \dots C_{T5}]$. The difference between two gaits is measured as the normalized mutual information between the corresponding gait vectors (eq. 2c).

Encoding schemes

The generative encodings for evolving hexapod locomotion controllers are based on compositional pattern producing networks (CPPNs) (Stanley, 2007). CPPNs abstract the processes of embryonic development by determining the attributes of phenotypic components as a function of their geometric location in the individual, instead of simulating complex inter-cellular interactions.

The CPPN genome is represented as a directed graph, comprising a set of *Sine*, *Gaussian*, *Sigmoid*, and *Linear* type of nodes, connected by weighted links. The node type indicates the activation function applied to the sum of its weighted inputs, to compute the node output. Selected activation functions can succinctly encode a wide variety of phenotypic patterns, such as symmetry (e.g., a Gaussian function) and repetition (e.g., a Sine function), that evolution can exploit. Mutations to the CPPN genome can change the connection weights and node type, and add or remove nodes from the graph. Consequently, the topology of the CPPN is unconstrained, and can represent any possible relationship between the input coordinates of the phenotypic component and its output attributes (see details in Stanley (2007)).

In this study, the CPPN genotype is mapped to two very different phenotypes, the conventional Artificial neural networks (ANNs), and the Single-unit pattern generators (SUPGs). The SUPG is a new type of macro-neuron introduced by Morse et al. (2013) to genetically encode spatiotemporal oscillatory patterns.

Encoding ANNs with CPPNs (minimal HyperNEAT):

The first generative encoding scheme evaluated is a simplified version of HyperNEAT indirect encoding² (Stanley et al., 2009; Clune et al., 2011; Yosinski et al., 2011). The CPPNs encode the weights of a fixed topology, single-layer feedforward ANN, featuring 2-D cartesian grids of inputs, hidden and output neurons (Fig. 2). Neurons are placed in a geometric space termed the *substrate*, so that each neuron in a layer has a distinct (x, y) coordinate. In addition, the placement of the input and output neurons is meant to reflect the hexapod robot morphology. The CPPN is iteratively input the positions of all source (x_1, y_1) and target (x_2, y_2) neurons in proximal layers, along with a constant bias, and it outputs the corresponding weights of the input-hidden and hidden-output neuron connections (see Fig. 2).

The ANN receives as input the previously requested angles (actual angles unknown) for each of the 12 pivot joints of the robot (\mathbf{s}_1 and \mathbf{s}_2 , for 6 legs). In addition, sine and cosine waves of frequency 1 Hz are also input to the ANN, to facilitate output periodic oscillations. The output from the ANN at each time-step are 12 numbers (one for each of \mathbf{s}_1 and \mathbf{s}_2 , on each of 6 legs) in interval [-1,1], that are scaled to the allowable angular range of the corresponding motors, and indicate the next position of each motor.

In preliminary experiments, this encoding evolved ANNs that exhibited high frequency output oscillations (in excess of 20 Hz). In the resultant gaits, the robot could traverse large distances by vibrating its legs rapidly, and in unison. To resolve this problem, and as suggested by Yosinski et al. (2011), we generated joint angular positions with a time-

²The CPPN is evolved with a simple multi-objective evolutionary algorithm, instead of the NEAT method (details in Tonelli and Mouret (2013)).

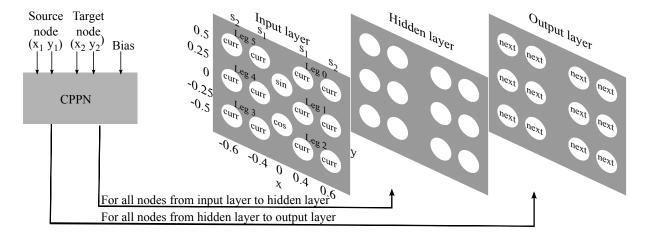

Figure 2: Encoding ANNs with CPPNs (inspired by Clune et al. (2011); Yosinski et al. (2011)). Inter-neuron connection weights are encoded as function of the position source and target neurons of each neural connection. The CPPN outputs the weights of input-hidden and hidden-output neuron connections, for each source (x_1, y_1) and target neuron (x_2, y_2) in proximal layers. The ANN is input the requested angles of the previous time-step for the first two servos $(s_1 \text{ and } s_2)$ on each leg, and a sine and cosine wave. The output neurons specify the new joint angles for the current time-step.

step of 15 ms, by averaging over four consecutive pseudopositions generated at 3.75 ms intervals. The number of evolved ANN controllers outputting high frequency oscillation was thus reduced.

Encoding SUPGs with CPPNs: In the second generative encoding scheme evaluated, the CPPN encodes the attributes of a SUPG. The SUPG is a macro-neuron (Fig. 3) that upon being triggered, produces a single cycle of a CPPN encoded activation pattern. Consequently, the repeated triggering of the SUPG results in temporal oscillations, that can be used to drive the motors of a legged robot (Morse et al., 2013).

In this encoding, the CPPN is input the position (x,y) of the SUPG in the substrate, and the elapsed time (in interval [0,1]) since the SUPG was last triggered (Fig. 3a). During the period of the SUPG, its internal timer ramps upwards with each simulation time-step, from an initial value of 0 to a maximum value of 1 (Fig. 3b). Therefore, the resultant activation pattern output by the SUPG is a function of both, its position in the substrate, and the time since the last cycle was initiated.

Applying the SUPGs for hexapod locomotion, the substrate comprises 12 SUPGs positioned to reflect the robot morphology (Fig. 3c). The outputs of the SUPGs at each time-step specify the desired angles for the first and second servos (s_1 and s_2), on each leg of the robot. The two SUPGs on each leg of the robot are triggered by the corresponding foot touching the ground, resulting in a closed-loop control. Finally, to avoid all the SUPGs being triggered simultaneously, the first trigger to each SUPG is delayed by an offset. In this study, the offset output of the CPPN is determined for the s_1 SUPG on each leg by supplying its coordinates as input, and setting the time input to 0. The same offset value

is also applied to the s_2 SUPG on the leg, allowing both the oscillators on each leg to start simultaneously.

Direct encoding: Locomotion controllers evolved with direct encoding are designed to be simple, wherein the actuation along each DOF of the robot is governed by the periodic signal of an uncoupled amplitude controlled phase oscillator. For an oscillator controlling servo \mathbf{s}_j on leg l of the robot, we have:

$$\ddot{\alpha_{lj}} = \beta \left(\frac{\beta}{4} \left(\mathbf{A}_{lj} - \alpha_{lj} \right) - \dot{\alpha_{lj}} \right)$$
 (3a)

$$\gamma_{lj} = \alpha_{lj} \cos \left(2\pi \left(t + \phi_{lj}\right)\right) \tag{3b}$$

where α_{lj} and ϕ_{lj} denote the amplitude and phase of the oscillator, A_{lj} represents its intrinsic amplitude, and γ_{lj} represents the control signal with frequency of 1 Hz. The uncoupled oscillator amplitude α_{lj} converges to the intrinsic amplitude A_{lj} at rate determined by positive constant β (set to 10 for rapid convergence). The Euler integration method with a step-size of 20 ms is used to solve the differential equation.

Hexapod leg actuation is governed by the differential equation model (eq. 3) instead of a standard periodic function (e.g., Koos et al. (2013)), to allow for smooth transitions in amplitude and frequency of the control signal between different gaits and to investigate the effects of coupling between oscillators, in our future work.

There are four evolved parameters $(A_{l1}, \phi_{l1}, A_{l2}, \phi_{l2})$ on each leg $l \in \{0...5\}$ of the robot. Consequently, a directly encoded controller for the hexapod robot is fully represented by 24 parameters.

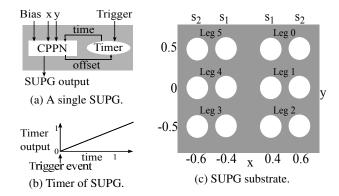

Figure 3: Encoding SUPGs with CPPNs (inspired by Morse et al. (2013)). (a) The SUPG output is a function of its coordinates (x,y) in the substrate, and the elapsed time since last trigger (output of Timer). The time of first trigger is determined by an offset. (b) Once triggered, the SUPG timer ramps upward linearly from 0 to 1 and stays there, until it is re-triggered. (c) Positions of the 12 SUPGs in the substrate, outputting the desired angles for the first two servos (\mathfrak{s}_1 and \mathfrak{s}_2), on each leg of the hexapod.

Experiments

We conducted 8000 generations of artificial selection in populations consisting of 100 individuals. Our aim was to evolve controllers for the hexapod robot to walk forward, evaluated for a period of 5 s (334 time-steps). The nondominated sorting genetic algorithm II (NSGA-II) was used to simultaneously optimize the following three objectives:

$$\text{Maximize} \begin{cases} -F_i \\ -|\Theta_i| \\ \frac{1}{N} \sum_{i=0}^{j=N} D(B_i, B_j) \end{cases}$$
 (4)

where for individual i in the population, F_i is the fitness computed as the distance between the final position of i and a goal located 25 m directly in front of the robot's initial position, Θ_i denotes the angle of the robot's trajectory with respect to the normal forward walking direction, $D(B_i, B_j)$ is the hamming distance between the binary gait vectors of individual i and j, and N is the size of the population.

In eq. 4, the first and second objectives reward individuals to walk forward large distances towards a goal, unattainable by the robot within the experiment evaluation time. The third objective is introduced to facilitate the exploration of diverse solutions and avoid premature convergence (Mouret and Doncieux, 2012).

Artificial selection was conducted in 20 independent replicates, for each of the three encodings. Performance and evolvability analysis are reported for the best individual of each replicate, selected to have the highest fitness in the population, and with an angle of trajectory in the range

of $\pm 1^{\circ}$ (simulation source code can be downloaded from http://pages.isir.upmc.fr/evorob_db.)

Individual performance

In all the encodings, the performance of the best individuals rapidly increased with a quasi-stable equilibrium being reached with less than 5000 generations of selection (Fig. 4a). Additionally, the directly encoded individuals converged more rapidly as compared to those encoded with ANN and SUPG schemes (Fig. 6a). After 8000 generations, the performance of the Direct, ANN and SUPG encodings, was 1.94 ± 0.18 , 2.93 ± 1.60 and 2.78 ± 1.43 meters, respectively (Median \pm IQR, see Fig. 4b). Amongst the three encoding schemes, the directly encoded individuals received the lowest performance (Mann-Whitney test, d.f. = 38, all p < 0.001), while no significant difference in performance was detected between the two generative encoding schemes.

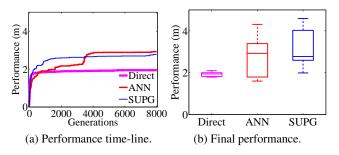

Figure 4: Performance in forward displacement for the Direct, ANN, and SUPG encodings: (a) Median performance for the 8000 generations of evolution; and (b) Performance of encodings at generation 8000.

Importantly, the frequency of the directly encoded oscillations governing leg actuation was prefixed at 1 Hz (eq. 3b). By contrast, the individuals evolved with generative encodings were capable of expressing higher frequency oscillations (2.56 ± 1.25 Hz for ANN, and 3.81 ± 0.73 Hz for SUPG), and the frequency of the gait may itself be under selection. Consequently, an assessment of the three encodings solely on the basis of the performance is biased, and other measures are needed to compare encodings.

Evolvability analysis

The evolvability provided by the encoding schemes is analyzed by mutating the best individual of each replicate at generation 8000, and reporting the following: (i) The proportion decrease in performance consequent to the mutation (eq. 1); and (ii) The gait diversity, computed as the mutual information between gait vectors of the original and mutated individual (eq. 2c). The individual is mutated 1000 times, in separate, independent instances. Finally, a kernel density estimation (Scott, 2009), is used to visualize the re-

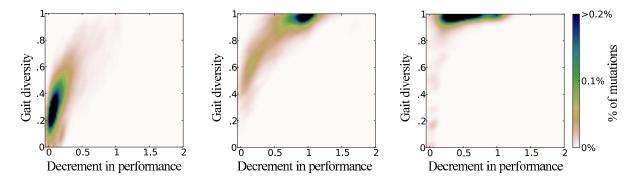

Figure 5: Gait diversity and the proportion decrease in performance, consequent to each of 20000 independent mutations, for the Direct (left), ANN (middle), and SUPG (right) encoding schemes, pooled from all 20 replicates.

sultant landscape of 20000 data points (1000 mutations \times 20 replicates), pooled together from all replicates.³

Across the three encoding schemes, the SUPG approach revealed the highest evolvability, with the capability to explore very different but viable gaits (see Fig. 5). In evolvability analysis with Direct encoding, a conservative exploration of the phenotype, limited to solutions close to the unmutated individuals was found (0.33 and 10.5\%, median gait diversity, and drop in performance, respectively). By contrast, the generative encodings were aggressive in the exploration of the phenotypic landscape, with the gait diversity of mutated individuals at 0.95 for ANN, and 0.99 for the SUPG encodings. However, differences existed in the severity of negative effects of mutations amongst the two encoding schemes. The ANN encoded individuals were sensitive to the effects of deleterious and lethal mutations⁴, resulting in a 78.9% drop in performance. In comparison, individuals evolved with the SUPG encoding were much more resilient to the negative effects of mutations, with a smaller decrement of 43.1% in performance following mutation.

Adaptation to faults

The significance of our measure of evolvability of the Direct, ANN and SUPG encodings was investigated by analyzing the adaptation of the evolved robot's gait, following the removal of one of its legs. We expect that for the encodings registering a higher measure of evolvability, the corresponding evolved individuals would require fewer generations to recoverer an effective walking gait.

In these experiments, the new populations comprised 100 mutated individuals of the best individual of each replicate at generation 8000. We conducted a further 10000 generations of artificial selection on the populations of amputee

hexapods (leg 1 removed). The number of generations required to regain an effective gait and the proportion of the original performance recovered, was analyzed.

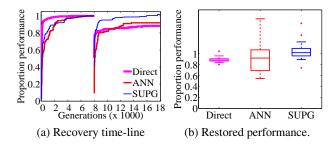

Figure 6: Recovered performance in forward displacement with the removal of leg 1 (legs numbered in Fig. 1a), for the Direct, ANN, and SUPG encodings: (a) Median proportion of performance before (left), and after (right) leg removal; and (b) Proportion of performance recovered 10000 generations after leg removal.

In the 10000 generations of selection, all the three encodings were capable of recovering the majority of their original performance (see Fig. 6a). After 10000 generations post leg removal, the recovered proportion of performance of the Direct, ANN and SUPG encodings, was 0.88 ± 0.04 , 0.92 ± 0.38 , and 1.02 ± 0.14 , respectively (Median \pm IQR, see Fig. 6b). Furthermore, amongst the three encoding schemes, the SUPG encoded individuals recovered the most of their original performance (Mann-Whitney test, d.f.=38, all p<0.001), while no significant difference in recovered performance was detected between the Direct and ANN schemes.

In order to analyze the recovery rate of ampute hexapods, in Fig. 7 we have plotted the performance lost immediately after leg removal in each of 20 replicates (horizontal axis) and the number of generations required to recover 90% of the original performance in each replicate (vertical

 $^{^3}$ Bivariate density estimation, with Gaussian type kernels over a grid of 100×100 equidistant points.

⁴Lethal mutations result in performance drops in excess of 100%, corresponding to the failure of any forward movement by the robot.

axis). The directly encoded individuals could make a 90% recovery in only 6 of 20 replicates, and suffered a median drop in performance of 60.9% immediately following leg removal. By contrast, the ANN and SUPG generative encoding schemes were better able to recover the loss in performance following amputation. In experiments with ANN encoding, 12 of 20 replicates recovered 90% of their original performance in 4392 generations (median for all replicates), despite a drastic initial loss in performance of 93.9%. The SUPG encoded amputee hexapods exhibited the fastest recovery, with 18 of 20 replicates being able to make the mark in 559 generations (median for all replicates), after incurring a smaller initial drop in performance of 67.3% consequent to leg removal.

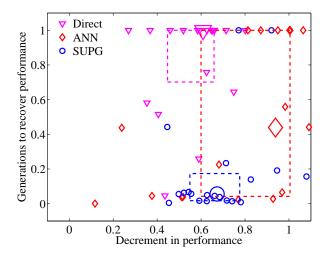

Figure 7: Proportion of performance lost immediately after leg removal and the number of generations (of 10000) required for recovery, in each of the 20 replicates (small markers), and the corresponding medians (large markers), for the Direct, ANN, and SUPG encoding schemes. The bounding boxes extend from first to third quartile.

Discussion

We investigated the evolvability provided by generatively encoded ANNs (Clune et al., 2011; Yosinski et al., 2011) and SUPGs (Morse et al., 2013), and a direct encoding, quantifying both, (i) the robustness to deleterious mutations, and (ii) the variations in the phenotypes after genetic change, for the hexapod locomotion problem. The significance of our measure of evolvability was evaluated by the individual adaptation response to morphological changes, not previously encountered by the hexapod.

Our results revealed a direct relationship between the estimated evolvability, and the capability of an individual to adapt to severe changes in its morphology, simulated by the amputation of one of its legs. Amongst the three encodings evaluated, SUPGs exhibited the highest evolvability,

and were best able to recovery following leg removal. In all but two replicates, the individuals were capable of recovering 90% of their original performance, and did so almost an order of magnitude faster than the other encodings, perhaps consequent to the closed-loop control ingrained in the SUPG encoding scheme. Such a mechanism would attempt to reform deleteriously mutated gaits, and consequently buffer the individual from the negative effects of such mutations. However, the effects of such a self-correction mechanism on evolvability needs further investigation.

The generatively encoded ANN and SUPG individuals achieved high performance gaits, when evolved for the symmetric hexapod robot. However, the performance recovery following leg removal was appreciably different between the two encoding schemes. The longer recovery of ANN individuals may be consequent to the resultant unsymmetrical and irregular hexapod morphology, a region of the problem geometry space wherein ANN generative encodings have been shown to perform poorly (Clune et al., 2011). Consequently, the damage recovery of ANN-encoded individuals would improve in situations wherein changes to the hexapod morphology preserve its symmetry (such as the removal of two middle legs). The outcome of such a scenario needs to be explored further.

For our measure of evolvability, we mutated the individuals with a predetermined mutation rate, tuned to allow a speedy convergence of the evolved solutions. This is a critical consideration, as variations to the mutation rate can affect the viability and gait diversity of generated mutants. Preliminary results suggest that with an increase in mutation rate, the peak of the distribution of mutants shifts towards more diverse gaits. However, the overall shape of the distribution, highlighting desirable regions of the evolvability landscape, remains the same for all three encodings. A rigorous analysis on the effect of variations in mutation rate and size (e.g., small mutations to many genes, or large mutations to a few genes) on the evolvability landscape, is part of our future work.

In this study, we present a novel approach to visualize the evolvability of a genotype-phenotype map, to analyze simultaneously the quality of genetic mutations, and the quantity of phenotypic variation generated. Our measure of evolvability may allow the selection of an encoding capable of producing adaptable individuals, when a inter-encoding performance comparison is no longer sufficient. In our model, the phenotypic variation was associated with the mutual information between hexapod gaits, but the diversity may be similarly computed for bipedal and quadrupedal robots, and for other qualities, such as the final position of a robot in a maze navigation task (Lehman and Stanley, 2011; Mouret and Doncieux, 2012). In this way, we hope our work may serve as a stepping stone for further research on evolvability, applied to a wide range of problems in the field of evolutionary computation.

Abstract

When studying different species in the wild, field biologists can see enormous variation in their behaviors and learning abilities. For example, spotted hyenas and baboons share the same habitat and have similar levels of complexity in their social interactions, but differ widely in how specific vs. general their behaviors are. This paper analyzes two potential factors that lead to this difference: the density of connections in the brain, and the number of generations in prolonged evolution (i.e. after a solution has been found). Using neuroevolution with the NEAT algorithm, network structures with different connectivities were evaluated in recognizing digits and their mirror images. These experiments show that general intelligence, i.e. recognition of previously unseen examples, increases with increase in connectivity, up to a point. General intelligence also increases with the number of generations in prolonged evolution, even when performance no longer improves in the known examples. This outcome suggests that general intelligence depends on specific anatomical and environmental factors. The results from this paper can be used to gain insight into differences in animal behaviors, as well as a guideline for constructing complex general behaviors in artificial agents such as video game bots and physical robots.

Introduction

All species have special abilities that help them survive in their ecological and social niche. Such abilities can be termed *domain-specific intelligence*. For example, spotted hyenas are extremely capable hunters, whether alone or in a pack, but they are poor at tasks in new domains to which they have not been exposed. On the other hand, baboons, which share the same habitat and have similar social structure, are very good at solving new tasks that they have never seen before, such as finding food that is hidden from them by human beings. This ability to solve novel problems outside of specific cognitive domains is called *domain-general intelligence*. Thus, the extent of general intelligence is different in different species, even those in similar environments.

A prevailing theory is that domain-general intelligence emerges from the interaction of multiple processes or modules in the brain (Kaufman et al., 2011; van der Maas et al., 2006). So far, there have been few attempts to analyze or

verify this theory through computer simulations. In this paper, neuroevolution techniques were used to study the evolution of general intelligence. These simulations investigated the effects of different network structures and prolonged evolution on the ability to solve a new task never seen during evolution. Network connection densities were varied to resemble the interconnectivity of brain modules in different species. The length of prolonged evolution after the old tasks had been solved was also varied. It was discovered that the performance on the new task, i.e. general intelligence, increased with increasing connection density, up to a point. Performance also improved with prolonged evolution even though fitness in the old tasks no longer improved. These results suggest that general intelligence may emerge due to specific anatomical and environmental factors.

Neural networks were employed in these experiments because they have been used to simulate brain structures previously with success(Amit, 1992; Miikkulainen et al., 2005). In addition, neuroevolution has been used to study predatorprey interactions and the evolution of complex behaviors in animals (Rawal et al., 2010; Rajagopalan et al., 2011). Thus the insights from this paper should be useful in building better better models of intelligent behavior in the wild, as well as to develop more realistic artificial agents in video games or robotics.

This paper is organized as follows. The next section examines the biological background and prior work in analyzing the origins of general intelligence in animals. The neuroevolution architecture and algorithm used in this paper are discussed in the section after that. The two sections following that lay out the hypotheses and the experimental setup used to test them. The Results section describes the actual experiments performed as well as the results obtained.

Biological Background

Animals in their natural habitat face many different kinds of problems for which special abilities may be required. Indeed, all species exhibit specialized cognitive skills that are essential for their survival. These skills fall under the realm of domain-specific intelligence, and may be activated or in-

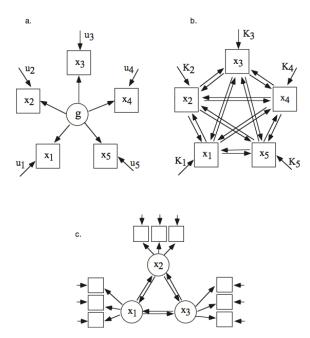

Figure 1: Three models of the positive manifold: (a) the standard g model, which shows the underlying g factor that influences all cognitive processes, (b) the mutualism model, showing the interaction between various mental mechanisms, and (c) the extended mutualism model, where only the latent processes interact. Squares and circles denote manifest and latent variables, respectively. Symbols x denote processes, y unique variances, and y resources (van der Maas et al., 2006).

hibited by specific circumstances arising in the environment. Each ability is thought to be controlled by a particular module or area of the brain (Cosmides and Tooby, 2002). Thus, many animal species excel in solving certain problems, but not others.

In contrast to domain-specific intelligence, domain-general intelligence is the ability of an individual to solve new problems. Some animal species, for example, mice (Matzel et al., 2011) and primates (Reader and Laland, 2002), possess an underlying cognitive mechanism that helps them with associative learning and general problem-solving. Evolutionary biologists and behavioral ecologists have posited that domain-general intelligence consists of several linked domain-specific abilities (Cosmides and Tooby, 2002). It has also been hypothesized that general intelligence emerged from domain-specific capabilities evolving under complex evolutionary pressures. Primatologists argue that these pressures were specifically the complex social structures and labile social interactions required of primates (Dunbar, 2003; Byrne and Whiten, 1989).

Primates are well known to be superior to most other animals in their behavioral flexibility and ability to solve prob-

lems (Byrne and Whiten, 1989; Tomasello and Call, 1997). Moreover, they live in structurally complex groups. Therefore, social cognition seems to be related to general intelligence, implying that all animal species that live in similarly large and complex societies should possess primate-like cognitive abilities. However, this prediction is not always true. For example, the societies of spotted hyenas (Crocuta crocuta) are remarkably like those of cercopithecine primates such as savanna baboons (Papio anubis) with respect to size, composition, structure, and patterns of competition and cooperation (Holekamp et al., 2012). A host of studies have found that spotted hyenas and baboons have converged with respect to social cognition (Holekamp et al., 2007; Benson-Amram et al., 2011), but there is no evidence that their domain-general intelligence has converged. This result indicates that there may be some fundamental differences in the way the brain structures and cognitive faculties of different species have evolved.

General intelligence is most apparent in human beings. There is a significant positive correlation between abilities in various cognitive tasks (van der Maas et al., 2006): A good score on one cognitive test predicts good scores on all other cognitive tests. This empirical phenomenon is called the *positive manifold*, and it is unlikely to result from a strictly modular brain (Figure 1).

There are many theories regarding the origin of the positive manifold (van der Maas et al., 2006). One hypothesis is that there must be a single underlying mechanism in the brain on which general intelligence depends (van der Maas et al., 2006; Sternberg and Grigorenko, 2002). This factor is commonly denoted as *g* (Figure 1a). Another general intelligence model is called *mutualism* (van der Maas et al., 2006). In this model, the positive manifold arises from the interaction of multiple cognitive processes in the brain (Figure 1b). The extended mutualism model (Figure 1c) posits that *g* itself arises from the interaction between several latent cognitive mechanisms in the brain. These latent variables then influence the outwardly manifest variables that constitute general intelligence (van der Maas et al., 2006).

In this paper, neuroevolution was used to evaluate the theory of mutualism in the evolution of general intelligence. Neural networks represented the brains, and the neurons in them were the cognitive mechanisms that interacted to produce general intelligence. The extent of interactions was characterized by the number of connections between neurons in a neural network. Hence, a neural network with more connections was expected to perform better when tested on a general intelligence task. In addition, the amount of task-specific learning was varied to check whether there was a positive manifold or correlation between performance in that task and performance in a new cognitive task.

NeuroEvolution of Augmenting Topologies

Neuroevolution has previously been used to great effect for producing dynamic and intelligent behaviors in autonomous agents. For example, it has been used in simulated robot soccer (Whiteson et al., 2005), robotic battle (Stanley and Miikkulainen, 2004) and Ms. Pac-Man (Burrow and Lucas, 2009). It has also been used to simulate the hunting and social behaviors of animal groups (Rawal et al., 2010; Rajagopalan et al., 2011; Rawal et al., 2012). Thus, neuroevolution is a natural choice for modeling the emergence of general intelligence.

NeuroEvolution of Augmenting Topologies, or NEAT (Stanley and Miikkulainen, 2002), is a neuroevolution technique that optimizes not only the connection weights, but also the topology of a neural network. NEAT has the resources to add and delete both nodes and links. This technique was shown to be more effective than traditional neuroevolution methods that modify only the connection weights of neural networks (Stanley and Miikkulainen, 2002).

To make crossover between two neural networks with different topologies possible, their links have to be lined up according to the nodes they connect. NEAT makes this possible using a historical marker called a global innovation number which records when each connection was formed in the population's history. Speciation is also used to nurture new innovations in network structure that might otherwise be lost due to their low initial fitnesses.

In this paper, the NEAT algorithm was used to evolve simple neural networks. These networks were trained on one cognitive task, but tested on a different task to study their ability to adapt. The number of links in the neural networks was varied to analyze the effect of connection density on performance in general intelligence, or the testing phase. It is easy to manipulate the connectivity of networks in NEAT by changing the probability of adding new links. This ability makes it a good choice as the neuroevolution algorithm for this particular study.

Hypotheses

The experiments in this paper were conducted with the objective of simulating the early evolutionary processes in the brains of species with different levels of domain-general intelligence. With this goal in mind, two factors thought to influence general intelligence were tested. The following hypotheses specify the expected results:

1. The general intelligence should increase with the connection density.

Theories from differential psychology claim that more interaction between the various modules in the brain that have evolved for specific tasks results in higher domaingeneral intelligence (van der Maas et al., 2006). In the

simulations in this paper, a neural network with more connections between its neurons is expected to have perform better in the testing phase.

The general intelligence should increase with extended evolution.

As stated in the Biological Background section, performance in various cognitive tasks are found to be positively correlated with one another. If neural networks are evolved past the point where their performance in the known tasks has plateaued, they evolve to be more diverse, robust and efficient in these tasks (Watson et al., 2011; Lehman and Stanley, 2010). They are more resilient to changes in network function (such as mutations), and should be more resilient to changes in the input as well, and thereby more general. As a result, their performance in the testing phase should improve with prolonged evolution on the first task.

Experimental Setup

This section describes the experimental setup used for the experiments in this paper. As explained in the previous sections, the goal was to computationally explore theories from neurobiology and psychology about the evolution of domain-general intelligence. To simulate the evolution of animal brains, simple two-layer neural networks were evolved using the NEAT algorithm.

The connections between the neurons simulated the interaction of processes in the brain, and the length of prolonged evolution (i.e. evolution after a satisfactory performance had been reached) represented the opportunity to evolve generalized processes. In the testing phase, new input was presented to the neural network. These inputs were related to the old inputs, but were not shown to the neural network during evolution. The performance on the new input was taken as the general intelligence of that particular neural network. Fitness was defined as the percentage of inputs for which the correct output was produced.

All neural networks in the population were identical before the start of evolution. They each had a single hidden layer of neurons and sigmoidal activation functions. In the preliminary experiments, topology as well as weights could change through evolution. The later experiments involved the evolution of only the connection weights. Even when topology was evolved, only links were added or deleted; the number of hidden neurons was always constant. The population consisted of a single species of either 30 or 100 individual neural networks. This number and the number of species changed during the program's execution as part of the NEAT algorithm. Each experiment was run 20 times for each population of neural networks and their results were averaged.

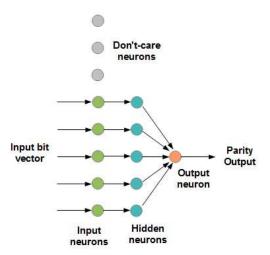

Figure 2: The initial network topology for the parity task. There are eight input nodes of which five are active, and three are don't cares. The five input nodes are connected to five hidden neurons, each of which is connected to the single output node. This preliminary task demonstrated that the topology-evolving approach would converge to similar architectures for this simple problem. Therefore, a fixed-topology approach in a more challenging task was necessary to test the hypotheses.

Results

Preliminary experiments were first conducted in the multibit parity domain to check what kinds of tasks and neural network architectures were most suitable for simulating general intelligence. In these experiments, both the connection weights and the structure of the networks were evolved using NEAT. Although links between already existing neurons were added or removed during evolution, neurons themselves were not created or deleted. Thus, the only factors affecting fitness were the number and location of the links, and the values of their weights. In this manner, interconnections between various brain modules were modeled. Insights from these experiments were then used to design a second set of experiments on a handwritten digit recognition domain.

Parity Task for Topology-Evolving Networks

For practical reasons, it is useful to start any simulation study with the simplest of tasks and the most basic neural network structures. After gaining insights on how to make them work, the algorithm and the task may be expanded gradually to more complex tasks. In this case, a simple logic function, multi-bit parity, served as a starting point to test the neural networks. In this task, the answer is 1 if the number of 1's in the input is even. The neural networks had eight neurons or nodes in the input layer, five nodes in the hidden layer and a single output neuron (Figure 2). Initially, each of the five

hidden neurons was connected to a different input neuron. Due to the sigmoidal activation function, the output neuron produced a real-valued number between 0 and 1. This value was taken to mean a 0 if less than 0.5, and a 1 otherwise. Of the eight input nodes, five were in use and had incoming multi-bit input, one bit at each node. Hence, there were 32 possible input bit strings. The other three nodes had as input fixed "don't-care" values. The neural networks were expected to ignore the don't-care inputs while successfully calculating the parity of the correct inputs.

Several combinations of evolution and testing scenarios were given to the networks and the percentage of testing phase inputs for which the network gave the wrong output (error) was recorded. Several neural network populations with different probabilities of adding links during evolution were tested in each of these. The idea was that networks with a higher probability of having links added would have acquired more links by the end of the simulation. Thus, according to our original hypotheses, these networks should perform better in the testing phase.

More specifically, the following experiments were performed in the parity task:

1. *Evolution task*: 22 of the 32 possible input bitstrings; don't care = 0

Test set: The other 10 bitstrings; don't care = 0

2. *Evolution task*: 22 of the 32 possible input bitstrings; don't care = 0

Test set: The other 10 bitstrings; don't care changes to 1

3. *Evolution task*: All 32 bit combinations; don't care = 0

Test set: All 32 bit combinations; don't care = 1

The purpose of conducting these different experiments was to evolve a neural network on one set of inputs and then test it on another, related set. If the neural network had evolved to generalize, the test problem should be solvable even if never seen before by the network. The performance on the new inputs was also expected to depend on the number of connections between the neurons of the network in question.

The main result was that all the different populations of neural networks (with the different probabilities of adding links during evolution) had similar performances during the testing phase. The reason was that all the networks had similar structure at the end of the simulation. Apparently, the NEAT algorithm is capable of adding links as needed for different network structures regardless of the probability of adding links. Moreover, although some links had been added for every network, the final structures still remained very simple. This result proved that the parity task was solvable by too simple a network structure. Therefore, a more

Figure 3: An example of the 8×8 bitmap encoding the image of a single digit, 7. The 1's represent black and the 0's represent white. This bitmap is concatenated into a 64-bit vector, which is given as input to the neural networks.

complex problem as well as a different neuroevolution strategy was needed to test the hypothesis that more connections mean more general intelligence.

Handwritten Digit Recognition Task for Fixed-Topology Networks

To avoid the problem with the parity experiments, in the second set of experiments, the topologies of all the networks were fixed and only the connection weights were evolved. Twenty trials of each experiment were run for each population and their results were averaged. The connection density remained the same between trials, but the individual connections could be different. Both feed-forward and recurrent neural networks were tested.

The recognition of handwritten digits, a well-known benchmark problem for neural networks, was chosen as a more challenging task, adapted for a test for domain-general intelligence. The inputs were not only the images of the digits, but also their mirror images. The mirror image of a single digit, 7, was left out of the set of inputs used during evolution and only used as a test input. The digit 7 was chosen for this purpose because the mirror image of 7 is not easily confused with other digits, and 7 is distinct from its mirror image (unlike 0, 1 or 8). If the neural network had evolved to recognize that some of its inputs were mirror images of other inputs, it should have no difficulty in recognizing a previously unseen set of mirror images. The performance during the testing phase is thus a good measure of the extent to which general intelligence has evolved in a neural network.

The handwritten digits were obtained from data stored in the NIST database. These images are taken from real-world

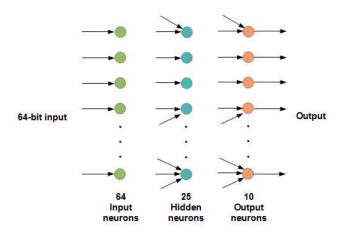

Figure 4: The network topology for the handwritten digit recognition task. There are 64 input nodes, 25 hidden neurons and ten output nodes. The connections between them are initially added at random based on the required connection density, but remain fixed thereafter. This more complex task and fixed-density architecture allowed testing the hypotheses about connectivity and prolonged evolution reliably.

data and therefore contain several noisy and distorted examples. The image of each digit was converted into an 8×8 bitmap representation, where 0 represents white and 1 represents black (Figure 3). The bits in the bitmap were then concatenated into a 64-bit vector, which was used as a single input to the neural network. Therefore, the neural networks in these experiments comprised 64 input nodes and 10 output nodes, representing a digit from 0 to 9. The digit corresponding to the node with the maximum value of output was considered the answer of the neural network to that particular input. The number of hidden neurons in each neural network was fixed at 25 (Figure 4). The number of distinct handwritten digit images shown to the networks during evolution was 5687, and the number of mirror images of 7 shown during the testing phase was 299.

The fixed topology of the neural networks meant that the effect of connection density on the testing phase performance could be easily measured. The second hypothesis, that the extent of prolonged evolution influences test performance, could also be verified by varying the number of generations for which the neural network was evolved after it had already evolved to recognize the inputs shown during evolution. The results of these experiments are shown in figures 5 and 6.

As predicted, the test performance increased with increasing connection density of the neural network. This result was true for both feed-forward and recurrent neural networks. After 65% density, however, the test performance started to decrease again (Figure 5). At the same time, the fitness on the training inputs also decreased, indicating

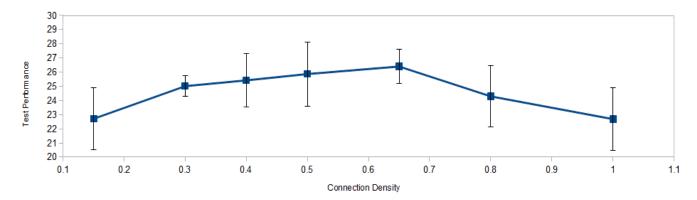

Figure 5: The average performance on the test phase (with unseen input) after evolving the network for 100 generations on the other inputs. Connection density fraction is on the *x*-axis and percentage of test input images the neural network identified correctly on the *y*-axis. The performance increases with increased connectivity up to a point, indicating more general intelligence.

that the decrease was not due to overfitting, but probably from the difficulty of evolving large numbers of connection weights.

Similarly, the test performance also increased with increasing numbers of generations for which the neural network was evolved. Evolution was continued beyond the 100 or so generations needed for networks with the optimal connection density (65%) to learn the training inputs. The performance on unseen inputs was plotted against number of generations for which the networks were evolved on the training inputs (Figure 6). It should be noted that there was no significant increase in the fitness over the evolution examples during the prolonged training. There was no effect on the results whether population size was 30 or 100. The fitness in Figure 6 for the point 0 on the *x*-axis (100 generations of evolution, stagnation just reached) is the same as the fitness for point 0.65 in Figure 5.

Thus, these results confirm that both denser connectivity and prolonged evolution result in networks that implemented more general solutions and therefore, more general intelligence.

Discussion and Future Work

The experiments described in the previous section support the hypothesis that fitness on a general intelligence task increases with increased connectivity in the brain. With the particular tasks with the simple neural networks in these experiments, more connections typically equals better generalization ability.

After a certain point, the testing performance decreases again. This is not due to overfitting but a different mechanism. The likely reason is that the neural network becomes

too complex for evolution to optimize. The networks have 64 input neurons, 25 hidden neurons and 10 output neurons each; at 0.65 connection density (i.e. with 65% of all possible connections), the number of connection weights that need to be evolved becomes very large. Excessive complexity would also explain why the populations of recurrent neural networks generally have a lower test performance than populations of feed-forward neural networks. Not only is the number of connections large, but the number of timesteps required for the network to settle is also higher.

From machine learning perspective, more connections in a neural network and prolonged training should result in overfitting, i.e. the network should not be able to generalize as well. It is interesting that the opposite effect is observed in the experiments in this paper: more connections and prolonged evolution results in more general behavior. Note that the task in this paper is not to simply interpolate between training examples, which is usually done in machine learning experiments, but to extend the behavior to a new class of examples. Such a task is more cognitive, and indeed the result is different. The task is still limited and it is difficult to demonstrate extensive general intelligence in it. But the fundamental property of general intelligence is the ability use behaviors in a novel context. Thus, it can be argued that the results indicate not just a generalization of neural networks, but the signature of general intelligence.

One significant insight gained from the above simulations is that the neural network architecture, the training algorithm, and the cognitive task employed to test general intelligence are all important. Further work is necessary to determine which combinations are most conducive to general intelligence. The main advantage of NEAT is the evo-

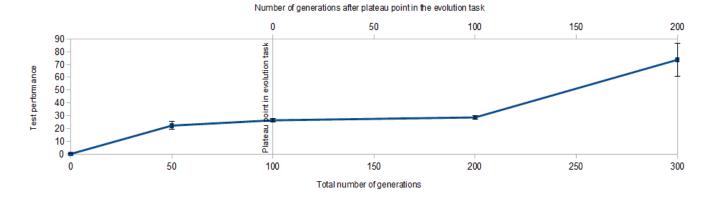

Figure 6: The average test performance of neural networks with connection density 65% after evolution for 50, 100, 200, and 300 generations on the other inputs. The training fitness usually plateaued at around 100 generations of evolution. The total number of generations is on the *x*-axis below the plot and the number of generations after fitness stagnation on the *x*-axis above the plot. The percentage of test input images the neural network identified correctly is on the *y*-axis. The performance on the test input increases with prolonged evolution.

lution of neural network structure, but since it is the level of interaction between many specialized modules that is being studied, a fixed-structure neuroevolution algorithm such as Multi-Component ESP (Gomez and Miikkulainen, 1997; Rawal et al., 2010) may be more beneficial. Different subnetworks of the same network can be evolved to perform different tasks, and their interconnections can be varied while the whole network is tested on a new domain-general task. Preliminary experiments with a hybrid NEAT-ESP algorithm are quite promising.

Similarly, the tasks themselves can be modified to resemble those faced by real animals in the wild better. Neuroevolution has already been used to evolve complex animal behaviors such as group hunting, communication with conspecifics and evading predators (Rawal et al., 2010; Rajagopalan et al., 2011; Rawal et al., 2012). Therefore, a task extension in this direction should be possible.

General intelligence approaches may ultimately be used to design robots or video game characters with realistic and complex behaviors. Such agents should be more versatile, more engaging, and more effective than is currently possible.

Conclusions

In this paper, two factors believed to influence the evolution of domain-general intelligence were tested using neuroevolution: connection density and prolonged evolution. The results indicate that increasing the number of connections leads to an increase in the general intelligence, up to a point. They also verify the hypothesis that prolonged evolution in similar cognitive tasks leads to better performance in a pre-

viously unseen task. Hence, it can be concluded that general intelligence is determined by specific anatomical and environmental factors that affect the evolution of an animal species.

The simulations from this paper can be extended in the future to more realistic tasks in environments resembling those in which real-life animal species live, gaining insight into differences observed in biology. Eventually, the same approach could be useful in creating intelligent behaviors for artificial agents in video games or robotics as well.

Reflective Grammatical Evolution

Christopher Timperley Susan Stepney

York Centre for Complex Systems Analysis, University of York, UK, YO10 5DD ct584@york.ac.uk susan.stepney@york.ac.uk www.yccsa.org

Abstract

Our long term goal is to develop an open-ended reflective software architecture to support open-ended evolution. Here we describe a preliminary experiment using reflection to make simple programs evolved via Grammatical Evolution robust to mutations that result in coding errors.

We use reflection in the domain of grammatical evolution (GE) to achieve a novel means of robustness by autonomously repairing damaged programs, improving continuity in the search and allowing programs to be evolved effectively using *soft* grammars. In most implementations of GE, individuals whose programs encounter errors are assigned the worst possible fitness; using the techniques described here, these individuals may be allowed to continue evolving.

We describe two different approaches to achieving robustness through reflection, and evaluate their effectiveness through a series of experiments carried out on benchmark regression problems. Results demonstrate a statistically significant improvement on the fitness of the best individual found during evolution

Keywords: reflection, open-ended evolution, grammatical evolution, robustness

Introduction

Our long term goal is to develop an open-ended reflective software architecture to support open-ended evolution *in silico*, as outlined in Stepney and Hoverd (2011). As a first step, we are making evolutionary systems more robust to evolved programs that contain errors. Here we describe an experiment using reflection to make simple programs evolved via Grammatical Evolution robust to mutations that result in coding errors.

Grammatical evolution (GE) is a metaheuristic search method belonging to the family of evolutionary algorithms. The evolutionary algorithm finds solutions to problems by evolving a population of individuals, each representing a potential solution to the given problem. In GE the individual genomes are typically represented as integer lists, decoded through a provided grammar into syntactically correct computer program phenotypes. Evolution operators may nevertheless produce semantically faulty programs. If these

faulty programs are removed from the population, any implicit heuristic information they may have gained will be lost to future generations. The alternative, examining the program phenotype to fix errors, is both complicated and grammar-dependent.

We instead use *reflection*, the ability of a program to inspect and modify its own code at run-time, to autonomously correct or *heal* the errors or *defects* that occur during the evolutionary process, in a grammar-independent manner. By being able to tolerate defects, a layer of *robustness* is incorporated into the search, allowing a wider range of mutations to be performed with less risk of losing good individuals from the population. This also allows less restrictive *softer* grammars to be used, which may improve locality in the search; traditionally such grammars would produce too many errors to be used effectively.

We demonstrate that reflection offers a viable mechanism for automatically correcting the dynamic population of individuals in GE. Using reflection, rather than a complicated grammar-dependent analysis of an individual's genotype and phenotype, allows the evolutionary process to remain unaware of the errors within its individuals' phenotypes and independent of how those errors are corrected. We achieve this isolation through a decentralised *robustness layer* that logically rests on top of the virtual machine of the programming language and below the layer of its programs.

The structure of the rest of this paper is as follows. We provide relevant contextual material on GE and reflection. We next describe two robustness layer designs, a global and a local one, to provide a robustness layer in Ruby programs. We then describe some evolutionary experiments, comparing these apporaches with a control case of no robustness layer, where faulty phenotypes are discarded.

Background

Grammatical Evolution

Grammatical Evolution (Ryan et al., 1998) is an evolutionary computation technique, implemented as a variant of the Genetic Algorithm (GA). The genotype typically takes the form of a list of integers, and the phenotype is produced by mapping the genotype to a derivation of a given grammar. Typically this grammar is used to model the grammar of a given programming language and the resulting derivations form syntactically valid programs in that language.

Unlike Genetic Programming (GP), another EA variant that directly represents and operates on individuals as computer programs (typically using a tree-like structure), GE's genotype separates the program structure from the evolutionary process. This allows programs to be evolved using arbitrary forms and languages, beyond LISP-style tree structures, and allows the GE representation to be used with non-evolutionary meta-heuristics to produce programs (Dempsey et al., 2009), such as particle swarm optimisation (O'Neill and Brabazon, 2006).

Mapping Process Individuals are mapped to their phenotype through the use of a Backus-Naur Form grammar. The values v from the list of integers are sequentially read off from left-to-right and used to select the next production rule to use from the grammar; at each step, the rule at index i is selected, where $i = v \mod m$, and m is the number of production rules available.

This process of derivation continues until one of the following situations occur:

- The mapping is completed, and all non-terminals have been transformed into terminals, producing a complete phenotype.
- The list of integers has been exhausted, but the mapping is incomplete. Usually in this case, the list is wrapped and its alleles are reused, allowing the derivation process to continue (Dempsey et al., 2009); however, this reduces locality within the chromosome, since codons may possess different meanings. An alternative is to cease the mapping process, but this produces a large number of incomplete and invalid derivations. Another alternative is to sample new codon values when they are required and to append these values to the end of the genome.
- A critical number of codons have been consumed. The derivation process is halted and the individual is assigned the worst possible fitness value; this mechanism prevents extremely long derivations from occurring.

Grammars Traditionally, GE uses heavily restricted, or *hard*, grammars designed to ensure syntactically and, as far as possible, semantically valid programs are always produced. Often these grammars are tailored to the domain of the specific problem being solved.

The performance of GE is highly sensitive to the choice of grammar down to its finest details (O'Neill et al., 2001). This problem, combined with the large domain of possible grammars, leads practitioners to use ad-hoc measures to design their grammar, if such considerations are given at all. Whilst *hard* grammars restrict the domain of the search, and

hence reduce the scale of the problem, their inflexibility can leave them trapped in a local optima and unable to escape.

We propose instead the use of *soft* grammars, that allow smaller changes to be made to the overall program. These grammars result in a larger number of semantically incorrect programs, however, so we combine this approach with a *self-repair* mechanism. This broadens the genetic land-scape and introduce flexibility into the phenotype. By incorporating such flexibility into the phenotype, neutral genetic drift is made possible; small changes to genotype may occur without dramatic consequence to the fitness of the individual. This transformation of the genetic landscape may allow the search to avoid the local optima of *hard* grammars, and may ultimately improve the performance of the algorithm.

Autonomic Computing

Self-healing is a form of *autonomic computing*, a term introduced by IBM in 2001 (Kephart and Chess, 2003), and used to describe computer systems capable of inspecting and modifying their behaviour in response to changing requirements. Inspiration for these systems came from the autonomic nervous system of the human body; an incredibly complex system composed of many interconnected components that seamlessly manage themselves to hide their complexity from us.

Kephart and Chess (2003) give four functional features that an autonomic computing system should possess:

- Self-optimisation: The ability to profile the usage and control the allocation of resources, to provide optimal service quality. Self-optimisation could also include rewriting software functions to reduce resource usage.
- Self-configuration: The ability to automatically configure components according to the context and environment of the system.
- Self-healing: The ability to automatically diagnose and correct faults.
- 4. **Self-protection:** The ability to recognise and protect itself from malicious attacks.

Whilst the grand vision of autonomic computing is yet to come to fruition, its individual features are beginning to be realised. Much of this effort has been directed towards the self-healing aspect of autonomic computing, in the field of *resilient software*, which seeks to address the inherent fragility suffered by all computer systems, by developing simple and lightweight alternatives to the difficult robustness and fault tolerance techniques employed in safety-critical system, which often involve additional hardware.

Adaptive Software Systems Haydarlou et al. (2005) proposes the use of *adaptive software systems*, which modify their own behaviour in response to errors and environmental

changes with the help of an adaptive plan describing what modifications should be made. Where such systems have been used, they have typically employed a fixed adaptive plan, pre-designed by a human programmer. An alternative, outlined in Haydarlou et al. (2005), involves using genetic programming to evolve an adaptive plan to allow the system to autonomously adapt itself to new situations.

Fraglets Tschudin (2003) describes a radically different approach to creating a robust environment for hosting resilient software, capable of addressing the problems of soft faults and program adaptability from a pure software perspective, without the need for hardware fault tolerance measures. This is achieved by using a novel software execution model inspired by the interaction of chemical molecules, which places the ability to self-modify at the core of its design.

This model is composed of small computational atoms called *Fraglets*, which when combined through reactions, process both code and data. Each time program code is required, a new instance is dynamically loaded and executed rather than being stored in the memory of the computer. This allows the code to be easily manipulated by the program without the problems of accessing live code in the memory. Lost and failed Fraglet executions are handled by creating and executing a new instance of the affected Fraglet.

Metaprogramming and Reflection

Metaprogramming is the technique of writing computer programs which manipulate or write the code of other programs (Perrotta, 2010). These meta-programs are written using a *metalanguage*, which facilities the writing and manipulation of programs written in the target *object language* (Stump, 2009).

Reflection is the ability of an object language to act as its own metalanguage (Smith, 1982; Maes, 1987; Stump, 2009; Ferber, 1989). Reflective systems may exploit the ability of reflection to inspect and manipulate the functionality and implementation of the system itself. In some programming languages, such as Lisp and Ruby, this reflective system may be the programming language itself, allowing many aspects of the implementation and semantics of the language to be inspected, extended and redefined at run-time.

Design

Here we describe two designs for implementing a robustness layer through reflection: a centralised or "global" approach, and a "local" approach. We have implement both, and compared them through evolutionary experiments.

Following an analysis of several popular reflective programming languages, we have concluded that Ruby offers the richest suite of reflective capabilities and a natural tilt towards meta-programming, making it an ideal language to explore the robustness layer approach.

ARITHMETIC FUNCTIONS

```
⟨op⟩ ::= 'add' | 'sub' | 'mul' | 'div'
# SOFT GRAMMAR
⟨program⟩ ::= ⟨block⟩
⟨block⟩ ::= ⟨fcall⟩ | ⟨float⟩ | ⟨var⟩
⟨fcall⟩ ::= ⟨string⟩ '(' ⟨fargs⟩ ')'
⟨fargs⟩ ::= ⟨block⟩ ', '⟨fargs⟩ | ⟨block⟩
⟨string⟩ ::= ⟨char⟩⟨string⟩ | ⟨char⟩ | ⟨char⟩
⟨float⟩ ::= ⟨nz_digit⟩⟨integer⟩ '.' ⟨integer⟩
| ⟨digit⟩ '.' ⟨integer⟩
⟨integer⟩ ::= ⟨digit⟩⟨integer⟩ | ⟨digit⟩
⟨char⟩ ::= 'a'..'z'
⟨digit⟩ ::= 'a'..'9'
⟨nz_digit⟩ ::= '1'..'9'
⟨var⟩ ::= 'x' | 'y'
```

Figure 1: Soft grammar used throughout paper.

```
 \begin{array}{l} sdd(afg(mua(x, mua(x, x, y)), juli(x, x)), \, x) \rightarrow \\ add(add(mul(x, mul(x, x)), mul(x, x)), \, x) \rightarrow \\ x^3 + x^2 + x \end{array}
```

Figure 2: An example of an evolved program, its effective form when using robustness measures, and its equivalent symbolic expression.

Here we investigate the use of these robustness measures with Ruby programs created via GE using a soft grammar (Figure 1). The only methods actually supported are the arithmetic functions (Figure 1), which take two arguments. The soft grammar can produce programs with method names that are arbitrary character strings, taking different numbers of arguments. (The long-term aim is to allow methods to mutate gradually into different methods; this is a first study.) To support this grammar, the robustness measures handle missing method errors, by mapping to an existing method, and incorrect argument errors, by truncating or padding the argument list. An example of a program evolved using the soft grammar is given in Figure 2.

Global Approach

The global approach achieves robustness by autonomously intercepting all exceptions thrown by monitored methods and applying fixes aimed at removing the root cause of the problem, calculated using details of the fault. This process can be seen as a form of *self-healing*, where the robustness layer *diagnoses* problems based on their details and automatically *heals* those problems by modifying the *damaged*

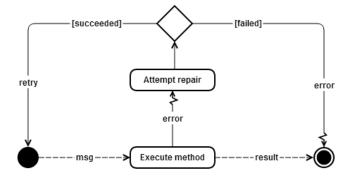

Figure 3: An overview of the global robustness layer design.

source code.

All calls to a *protected* method are routed through the global robustness layer, which attempts to execute the method according to its normal semantics.

- In the event of a fatal exception, the robustness layer becomes active and diagnoses the fault before calculating a suitable candidate fix to the issue.
- After the fix has been applied, the kernel attempts to call
 the modified method once again. In the event a subsequent error occurs, the process of diagnosis and repair is
 repeated, until either the method no longer produces errors during its execution, or till a maximum number of
 successive repairs has been reached.

Modifications made to the affected method during its "protected execution" may then be saved by the original method, removing the need to repair the method for successive calls. This ability proves useful for problems where the candidate solution is executed a number of times during evaluation, such as in regression problems.

Architecture

This layer is composed of three components which interact to examine the behaviour of protected method calls and to apply corrective measures in the event of their failure to prevent the program from crashing. These three components are:

Detection: Detects the occurrence of a specific type of fatal error within the affected method.

Diagnosis: Uses details of the error to determine its root cause within the source code of the affected method.

Repair: Uses the error diagnosis to apply corrective modifications to the source code of the affected method.

Instructions on how to detect, diagnose and repair specific types of errors are supplied to these components in the form of *error strategies*.

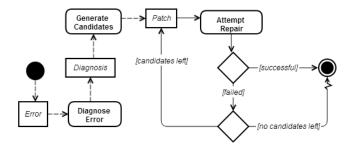

Figure 4: Architecture of the global robustness layer.

Immediately after an exception is thrown by a protected method, its details are passed to each of these error strategies, which try to detect if a certain type of error has occurred, the region of the source code responsible for producing the error, and how that code can be modified to remove the cause of the error.

After passing details of the error and method call to each error strategy, a set of candidate fixes are produced which are exhaustively tried until either the original error is no longer present, or there are no fixes left, in which case the original exception is thrown again, or a threshold number of tries is reached (10 in the work reported here).

Global Error Handling

The grammar as defined can produce two specific errors.

Missing Method Calls. Calls to non-existent methods are dealt with by changing all instances of the method name used to the name of an existing method that has with the lowest Levenshtein distance to the original.

Incorrect Number of Arguments. This is handled by reducing calls with too many parameters to the correct size, and padding calls with too few parameters with zeroes.

This transformation process manipulates the deepest method calls first (i.e. method calls that are used as parameters to other calls) to ensure that the resulting program is well-formed and that all calls to the affected method use the correct number of arguments.

Local Approach

Whereas the global robustness layer waits for a protected method to encounter a fatal error before attempting to repair the region of source code responsible for its cause, the local robustness layer is designed to achieve robustness by adapting the Ruby kernel itself to ensure that fatal exceptions are never raised in the first instance.

Instead of using a set of strategies to heal from specific errors, a set of changes are made to areas of the Ruby kernel capable of producing such errors, via a process known as "monkey patching" (Perrotta, 2010). By applying modifications to certain aspects of the programming language,

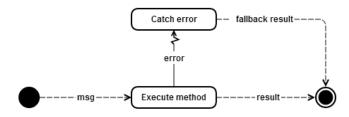

Figure 5: An overview of the local robustness layer design.

there is no need for a central entity to handle the execution and repair of protected methods; instead each fix acts independently, and the combination of them produces a thin robustness layer.

Local Error Handling

Missing Method Calls. To deal with calls to non-existent functions, the local approach implements Ruby's method_missing hook in the Module class, which is called when a requested method cannot be found inside a particular class.

The implementation of this function is similar to the approach taken to handling missing method calls in the global robustness layer; the function call is routed to the suitable function with the lowest Levenshtein distance to the requested function.

This re-routing mechanism also enforces a maximum distance constraint, which prevents the call from being routed to a function whose name is too far away from the requested method.

Incorrect Number of Arguments. Although the missing_method callback is capable of routing calls to non-existent functions towards their closest candidate function, this behaviour alone does not prevent an error being raised when the wrong number of arguments are then supplied.

To provide robustness against such errors, the implementation makes use of the method_added callback and the remove_method magic functions. Since there are no callbacks in place to handle function calls to existing functions with the incorrect number of arguments, the implementation instead captures and stores the object for every method added to the module in a private hash (indexed by the name of the method), via the method_added callback, before immediately removing the method from the module via the remove_method.

Every method call made to the module then invokes the missing_method callback, since methods are removed immediately after being added. The missing_method callback checks if the requested method "exists" by looking for its entry in the method hash; if there is no entry for the method then the closest candidate function is selected

Selection	Tournament

instead (if this is not possible then an exception is raised), before adjusting its arguments to agree with the arity of the selected method.

The arguments provided with the method call are made to fit with the expected argument structure by removing excess arguments from the end of the arguments array or by padding the arguments with zeroes to the right to compensate for missing arguments.

Experiments

To determine the effect of the robustness layer on the evolution trajectory during GE, and to test the design hypothesis, we have conducted a series of benchmark evolutionary experiments. To perform these experiments, we used our own EA implementation, written in Ruby, whose components are detailed in Table 1. (After some preliminary testing, we found that two-point crossover yielded better results than the more traditional single point crossover.)

These experiments compare the performance and behaviour of GE using global, local and no robustness measures, across a number of benchmark multi-modal symbolic regression problems from McDermott et al. (2012), listed in Table 2.

The genome is a fixed-length list of 100 integers, each taking a value between 0 and $2^{31}-1$. The mutation operator uses uniform random replacement, replacing the value of a codon with a uniform random value from the legal range. Each genome is initialised with 100 uniform random values from the legal range.

The evaluation function measures the fitness of individuals as the sum of squared differences between their actual and expected results using data from a pre-generated training set. Hence low values are better than higher values, and the best achievable fitness is 0.

Calibration

Good parameter choices for each robustness measure, chosen from a given set of possible parameter values (Table 3), were determined through calibration based on the Keijizer-15 benchmark.

Due to limits upon time and computational resources, an exhaustive search of the space of all possible parameters is not possible. Instead, we employed the Relevance Estimation and Value Calibration of Evolutionary Algorithm

Name	Vars	Objective Function	Training Set
Koza-1	1	$x^4 + x^3 + x^2 + x$	U[-1, 1, 20]
Koza-3	1	$x^6 - 2x^4 + x^2$	U[-1, 1, 20]
Keijzer-12	2	$x^4 - x^3 + \frac{y^2}{2} - y$	U[-3, 3, 20]
Keijzer-14	2	$8/(2+x^2+y^2)$	U[-3,3,20]
Keijzer-15	2	$\frac{x^3}{5} + \frac{y^3}{2} - y - x$	U[-3,3,20]

Table 2: Regression problems used to perform comparison. U[a,b,c] is c uniform random samples drawn from a to b, inclusive, for the variable.

Table 3: The space of evolutionary parameter values.

Parameters (REVAC) method (Nannen and Eiben, 2007) to calibrate the evolutionary parameters of our algorithm.

We used the REVAC parameters of Smit and Eiben (2010), except with fewer evaluations (1000 instead of 5000) to reduce computational effort (Table 4). To measure the expected performance of each parameter vector, we use the mean best fitness (MBF) across a number of runs.

The results of calibration are shown in Table 5, and are the evolutionary parameters used for the evolutionary experiments.

Main Experiments

After determining good evolutionary parameters to use for each of the robustness measures, we compared the performance of each of the measures over 100 runs of each of the benchmark functions.

Results from these experiments (Figure 6 and Table 6) show an improvement in both the median and minimum best fitness values when using either local or global measures, compared to using no robustness measures, for all benchmarks except Koza-3.

In all cases, the use of local robustness measures gave a minimum best fitness that was at least as good as that obtained using global robustness measures, and was usually better; this may be due to the local robustness layer's ability to cope with an unlimited number of errors within any given program.

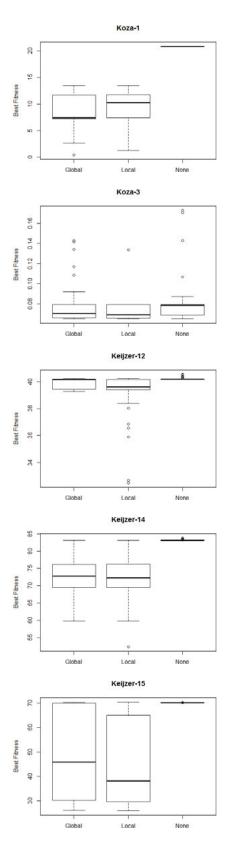

Figure 6: Distribution of best fitness values across 100 runs for each benchmark (low fitness values are better).

Crossover Rate	0.705	0.544	0.764
Population Size	161	161	189

Table 5: The parameter vectors for each measure.

Statistical Significance

We used the non-parametric Mann-Whitney U test to measure the statistical significance of the results, and to test the null hypothesis, H_0 : "the use of robustness measures have no effect on the fitness of the best individual found during evolution, compared to using no measures, when evolving a soft grammar."

We test to the standard 95% confidence level. We are performing 10 benchmark comparisons (Table 7), so we apply a Bonferroni correction and require each comparison to have a confidence level of 99.5%, or p < 0.005. Results given in Table 7 show that p < 0.005 on each benchmark except Koza-3. We reject the null hypothesis at the 95% confidence level, except for Koza-3.

Since using a large enough sample is usually enough to produce a statistically significant result, we also measure the effect size; we use the non-parametric Vargha-Delaney *A* value (Vargha and Delaney, 2000). From the results shown in Table 7, we can observe a large effect size between the use of global or local measures and no measures on almost of the benchmark functions, again except for Koza-3. These results suggest that the use of robustness measures produce a significant difference to the best fitness value found during evolution.

Conclusions

We have designed, implemented and tested two approaches that exploit reflection to perform self-repair in programs evolved using GE. We have demonstrated that both these measures have a statistically significant effect on the performance of GE using soft grammars in a series of benchmark functions.

Limitations

Although the local robustness layer is capable of handling the errors investigated here, to handle each error, a series of changes to the Ruby kernel has to be made. This approach is thus limited by the ability of the Ruby kernel to catch such errors. More complex errors, such as name errors raised when an unreferenced variable is used, require the robustness layer to know their context and to modify the original source code, and cannot be intercepted and dealt with on the fly. Since the global robustness layer is capable of examining the context of errors, and has the required ability to apply changes to the source code, it is better equipped to diagnose and repair a far wider category of errors.

Whilst the local robustness measures performed well across all of the problems, an unfortunate consequence of their changes to the Ruby kernel restricts them to a single thread during evolution. However, this shortcoming may be addressed using Ruby's recently introduced *refinement* functionality (Cooper, 2010), which allows kernel changes to be localised within a given context.

Another weakness of the local approach is that its inherent handling of errors on the fly means that the semantics of programs produced during evolution may not be the same when the local robustness layer is not deployed, since the code is never changed and errors will no longer be dealt with. One solution to this problem may be to pass individuals to a finaliser at the end of the evolutionary process, which analyses the execution of their associated program and monitors exceptions caught by each of the patches to determine the effective source code of the program.

Future Work

Having demonstrated the effectiveness of robustness measures when combined with soft grammars, we are now investigating the use of radically more expressive grammars, modelling subsets of an entire programming language, capable of universal computation.

We believe that by taking this approach, we can free the programmer from performing arbitrary decisions on their choice of grammar, and that entirely novel solutions to problems, beyond the scope of conventional hard grammars, may be discovered.

We are also investigating the use of techniques which allow the use of alternative meta-languages to perform correction, instead of the same language as the program, allowing programs to be evolved in arbitrary languages, regardless of their support for reflection.

Our long term goal is to use such techniques in the development of an open-ended an open-ended reflective software architecture to support open-ended evolution *in silico* (Stepney and Hoverd, 2011).

Studying the Evolvability of Self-Encoding Genotype-Phenotype Maps

Andrew M. Webb and Joshua Knowles

School of Computer Science, University of Manchester, UK andrew.webb@manchester.ac.uk

Abstract

We introduce a model of reproduction in which the genotypephenotype (G-P) map is able to evolve. In this model, Each organism implements a G-P map, determining how the organism is encoded in its genome. Crucially, it also determines how the G-P map itself is encoded. We call these maps 'self-encoding'. We relate this model to recent artificial life research, and back to the seminal work of John von Neumann. We simulate populations of organisms that have as their genome and G-P map the axiom and production rules of an L-system. The populations are given the task of optimizing a dynamic fitness function. Our purpose is to study whether the self-encoding property has any effect on the evolution of evolvability, and to look for other factors that lead to the evolution of G-P maps that confer evolvability. We find that evolvability does evolve, but only when we add constraints to the model.

Introduction

Our principal reason for studying the genotype-phenotype (G-P) map is its role in determining evolvability. We use Hansen's definition (Hansen, 2006):

"Evolvability is the ability of the genetic system to produce and maintain potentially adaptive genetic variants."

Higher evolvability means a greater probability of introducing adaptive variants. It is a variational property, related to the way that variations are introduced into the phenome.

Mutations in the genome are more or less random¹. The genome is an encoded form of the phenome, with the G-P map implementing the decoding function. It can potentially translate the random mutations in genome into directed changes in the phenome (Wagner and Altenberg, 1996; Hansen, 2006). For example, the G-P map might perform error correction when determining one attribute of the phenome, making it less variable than other attributes. Or it might use a single gene to determine two attributes, ensuring

that the two can only vary together. We will say that the G-P map *mediates* variation in the phenome, in the sense that it acts as a mediator between the random source of variation and variation that actually occurs.

A G-P map increases evolvability if it translates random mutations into suitably directed (i.e., sometimes adaptive) changes. Life on Earth is believed to have evolved towards higher evolvability through changes to the G-P map (Dawkins, 2003; Pigliucci, 2008).

When and how does evolvability evolve? In what kinds of environment does it happen? How can beneficial G-P maps be selected for when they only confer a future advantage and when selection can only act on current fitness? Recent work in artificial life has aimed to answer such questions by studying model organisms in which the G-P map can evolve. We introduce our own model of reproduction, in which the G-P map is 'self-encoding'; it determines how the G-P map itself is encoded in the genome.

The purpose of our research is to learn what factors lead to the evolution of G-P maps that confer greater evolvability. Our contributions are as follows.

- We describe and compare recent artificial life research in which model organisms within the Avida platform, or an extension of it, are studied with the purpose of understanding the evolution of the G-P map.
- We suggest potential problems with these models, and with using Avida to study the evolution of the G-P map in general.
- We introduce a model of self-reproduction in which organisms implement a 'self-encoding' G-P map.
- We simulate populations of these organisms, using L-system production rules as their G-P map, that evolve to optimize a dynamic fitness function. We find that evolvability fails to evolve unless we add constraints to the model.

Context and Related Work

In this section, we describe two models of self-reproduction used in recent artificial life research to study the evolution

¹There are conflicting definitions of 'genotype'. Here we use 'genome' to refer to the total genetic information of an organism, and 'phenome' to refer to the set of all traits of an organism. We use the established term 'genotype-phenotype map' to refer to the mapping between them.

of the G-P map. Since both models are based on the Avida platform, we also describe the default reproduction mechanism in Avida. For comparison, we describe the reproduction mechanism of John von Neumann's *universal constructor*.

Von Neumann's Universal Constructor

John von Neumann developed a two-dimensional, 29-state cellular automaton, and a structure within it that he called the *universal constructor* (Von Neumann and Burks, 1966). The universal constructor has, roughly, the following components.

- A one-dimensional 'tape' **G**, which in inactive; on its own, it doesn't do anything.
- An active 'machine' **P**, which consists of the following four components.
 - A 'decoder' A, which implements a decoding function.
 It reads the contents of the tape G, decodes the contents into the specification of a two-dimensional structure, and then builds that structure elsewhere in the cellular automaton.
 - The 'tape copier' B, which builds a copy of the tape G adjacent to the structure built by the decoder.
 - The 'coordinator' **C**, which coordinates the actions of the decoder and tape copier.
 - The 'ancillary machine' D, which can perform any arbitrary action as long as it doesn't interfere with the other components.

If the tape ${\bf G}$ contains an encoded description of ${\bf P}$, relative to the decoding function implemented by ${\bf A}$, then the pair constitute a self-reproducing machine; the part ${\bf B}$ constructs a copy of ${\bf G}$, and the part ${\bf A}$ decodes ${\bf G}$ to construct ${\bf P}$. In order to be a self-reproducer, the machine has to do two things. First, it has to implement a mechanism for copying the tape. Second, it has to implement a decoding mechanism that decodes the tape into a description of the tape-copying and decoding mechanisms.

This is a convincing model of biological reproduction that includes a G-P map. The analogy to life is as follows. **G** is the genome of the organism. **P** is the phenome. **A** is the G-P map, encompassing the genetic code and development processes. **B** is the mechanism for copying the genome. **D** is any behaviour of the organism not directly related to reproduction.

Mutations in **G** will manifest as a change in **P** in the offspring. Von Neumann noted that if the mutation affects only the ancillary machine, then the offspring will still be a self-reproducer. He believed that any mutation affecting the decoder would render the offspring infertile, as the decoding function it implements would no longer complement the encoding of **G**. A change to the decoder that leaves the offspring fertile corresponds to a change in the G-P map.

When G is mutated, how this manifests as a change in P of the offspring is mediated by the part A implemented

by the parent. This includes changes *to* part **A**; it mediates all variations in the offspring. Barry McMullin has been a proponent of studying this model of reproduction (McMullin, 2012).

Avida

Avida is a popular software platform for studying self-replication (Ofria and Wilke, 2004), in which each organism is a program in an assembly-like language. Avida has a cellular structure; each organism has its own private memory, and the organisms are arranged in a grid. The population of Avidans execute their instructions in parallel.

Avida simulations are initialized with a single, hand-designed self-replicating program called the *ancestor*. The default ancestor replicates by setting up and iterating over a copy loop, in which the 'copy' instruction is repeatedly executed to read from and write to successive memory locations. Once it has copied the entire contents of its memory, it executes the special *divide* instruction. This places a new child Avidan in a neighbouring cell, giving it the recently copied instructions.

Avidans can perform additional tasks as well as self-replication, and the experimenter can adjust the 'metabolic rate' of an organism (the rate at which it executes instructions) based on its performance on these additional tasks.

There are multiple types of mutation in Avida. The 'copy' instruction has a low probability of writing the wrong instruction, and 'cosmic ray' mutations can change any instruction in memory at any time.

An Avidan's sequence of instructions, being the hereditary information that is transmitted between generations, is its genome. The phenome of an Avidan is its behaviour when run. Since the genome determines the phenome, the G-P map is fixed.

As McMullin notes, in von Neumann's terminology, the **G** and **P** parts of an Avidan are the same, and consist only of components **B** and **D**. Avidans don't reproduce by applying a decoding function to an encoded description of themselves; they directly read and copy the contents of their own memory.

Implementing the 'von Neumann architecture' in Avida

Hasegawa and McMullin study a self-reproducing ancestor program based on von Neumann's model of reproduction (Hasegawa and McMullin, 2012). One part of the program, identified with **G**, is not executed but is read as data. The other part, identified with **P**, is executed, and does the following.

- 1. Enter a copy loop, identified with the tape copier **B**. Unlike the copy loop of the default Avidan ancestor, which copies the entire contents of memory, it only copies part **G**.
- 2. Apply a decoding function, identified with the decoder **A**, to **G**, and write the result to the region of memory adjacent

to the copy of G.

3. Execute the divide instruction.

During this process, mutations can happen in any part of the memory. Like von Neumann's constructor, Hasegawa and McMullin's ancestor has the property that when the part **G** is mutated, the change observed in **P** of the offspring is mediated by the decoding function implemented by the parent. However, it is possible for 'mutations' to happen directly in the part **P**. These mutations will cause changes to **P** that are unmediated by the decoding function.

One of their results is that populations quickly reverted to the self-inspection form of reproduction more commonly seen in Avida, without a decoding step.

Evolving the 'hardware' in Avida

Egri-Nagy and Nehaniv implemented a variant of Avida, in which each organism has its own set of data structures and its own high-level programming language, with instructions composed of Avida's lower-level instructions (Egri-Nagy and Nehaniv, 2003). When an organism is born, the first part of its memory is read as a specification of that organism's data structures and instruction set (its 'hardware'). The organism then starts executing instructions as normal.

They refer to the hardware specification as the 'G-P map', because it changes the result of executing the program (the 'genome'). However, unlike in Hasegawa and McMullin's work, the genome doesn't contain an encoded form of the G-P map; the mechanism of reproduction, like that of the default Avida ancestor, is to enter a copy loop that copies the entire contents of memory to the offspring, introducing copy errors.

The part labelled the 'G-P map' mediates the changes in the behaviour of the organism as a result of mutations in the genome. However, the G-P map itself is subject to random mutations, and the encoding of this part of the organism is fixed; variation in the G-P map is unmediated.

General Limitations

We suggest that Avida may not be an ideal platform for studying the evolution of G-P maps for the following reasons.

- Because it was designed to allow reproduction by self-inspection and copying, without a decoding step, this method of reproduction will inevitably be the most efficient in Avida. One of the results of Egri-Nagy and McMullin's work is that simulations initialized with their ancestor quickly become dominated by 'self-inspection' reproducers.
- The assembly-like programming language used by Avida isn't designed for easily expressing developmental processes.

Two of the types of mutation in Avida can act on any location in memory; for any Avidan that has parts equivalent to G and P, some mutations will happen directly in P, unmediated by the decoder.

Self-Encoding Genotype-Phenotype Maps

Here we introduce a model of reproduction in which each organism implements a G-P map, which determines how the organism is encoded in its genome. Moreover, it determines how the G-P map *itself* is encoded in the genome. For brevity, in the following we use 'genotype-phenotype map' and 'decoder' synonymously. We call the G-P maps 'self-encoding', and call the organisms 'self encoders'. The model differs from previous work in the following ways.

- The organisms do not implement a mechanism for copying their genome. In von Neumann's terminology, our organisms are missing part B. The reason is that we want to focus on part A, the decoder, and we know precisely what the behaviour of part B should be. The genome-copying step is built into the model.
- We initialize the population with randomly generated organisms, rather than hand-designed self-reproducing organisms, in order to avoid accidentally initializing the population in an evolutionary dead-end.
- Only the genome is mutated. All variation in the phenome is mediated by the decoder, including variation in the decoder itself.
- Rather than an assembly programming language, our model will use decoding mechanisms that are biologically inspired.

With the copying of the genome built into the model, and the initial decoder population initialized randomly, the initial state is analogous to a population of self-replicating RNA. The random initial 'decoders' are like active molecules that interact with the RNA to produce other molecules. The initial decoders are not self-reproducing; the emergence of self-reproducing decoders corresponds to the emergence of a developmental step on top of an existing replication mechanism.

Each organism in the model consists of a genome and a phenome. The phenome consists of a decoder, and another part that we will apply a fitness function to and adjust the metabolism of the organism based on the result. We call this part the *solution*. See Figure 1.

The population lives on a discrete grid, and is updated iteratively, in parallel, by looping over the grid. Algorithm 1 shows one such iteration. Fitter organisms are rewarded by 'stealing' update cycles from less fit neighbours. When an organism creates a new child, the child receives a mutated copy of the parent's genome. This genome becomes the starting point for the 'embryo', which is a working copy of the

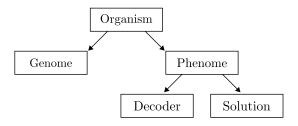

Figure 1: The structure of an organism in our model. Arrows indicate a 'contains' relationship.

data operated on by the parent's decoder. Each time a parent organism updates, it goes through one decoding step, applying its decoder to the embryo of its child. Later in the paper we give an example of a decoder being applied iteratively. When decoding is complete, the embryo is interpreted as the specification of a decoder and a solution. These are given to the child, and the solution is used to set the child's fitness. The child is then placed somewhere in the neighbourhood of the parent.

Algorithm 1 One time step of the simulation.

```

        organism p \leftarrow fitter of organism in cell and organism
2:
    randomly selected from 3 \times 3 neighbourhood
 3:
        if p has no embryonic child then
4:
             p.child.genome \leftarrow mutated\_copy(p.genome)
             p.child.embryo \leftarrow p.child.genome
 5:
 6:
        p.child.embryo \leftarrow p.decoder(p.child.embryo)
        if decoding is complete then
 7:
             (d, s) \leftarrow interpret(p.child.embryo)
 8:
9:
             p.child.decoder \leftarrow d
10:
             p.child.solution \leftarrow s
11:
             p.child.fitness \leftarrow fitness\_function(s)
             place child on grid in 3 \times 3 neighbourhood of p
12:
```

Selection is partly implicit, partly explicit; there is an implicit selection pressure to be an efficient and robust reproducer, and we explicitly apply selection pressures by rewarding organisms for the contents of their solutions.

The Decoding Mechanism

We use L-system production rules as the decoding mechanism. L-systems were first used to model plant development (Lindenmayer, 1968), but have since become popular as a more general model of development. An L-system consists of an alphabet, an axiom, which is a string in that alphabet, and a set of production rules. Each production rule specifies how to rewrite a substring to another substring. L-systems grow strings iteratively, starting from the axiom, by applying as many production rules as possible in parallel.

For example, an L-system might have the axiom

Α

and the production rules

$$\begin{array}{l} {\rm A} \rightarrow {\rm BA}, \\ {\rm B} \rightarrow {\rm A} \end{array}$$

The first few strings generated by this L-system are

A BA ABA BAABA ABABAABA

The L-systems we use are context sensitive (Prusinkiewicz et al., 1990), so the left-hand side of each production rule contains three symbols: the left context, the symbol to rewrite, and the right context. For example, the production rule

replaces the symbol \mathbb{B} , if it has an \mathbb{A} on the left and a \mathbb{C} on the right, with the symbols \mathbb{DEF} . We use context-sensitive L-systems because they allow recursive application of production rules, while also making it possible for the process of applying rules to terminate rather than recursing indefinitely.

Each organism has a set of production rules as its decoder, and its genome is used as the axiom of the L-system. Every L-system has the same alphabet of 10 symbols. The axiom of a parent is copied to its child and mutated. Starting with the child's axiom, the parent's production rules iteratively grow a string. One decoding step consists of applying as many production rules as possible in parallel.

When there are no more rules to apply, decoding is complete. The resulting string specifies both the production rules and the solution of the child. The symbol sequence AA is a punctuation mark separating the two parts. For example, the organism with the production rule

$$A < B > A \rightarrow DEFAADEF$$

operating on the axiom

ABA

will produce the string

ADEFAADEFA

which the AA punctuation separates into the strings

ADEF,
DEFA

with the first string specifying the production rules of the offspring, and the second string specifying the solution.

Since all production rules have three symbols on the left-hand-side and an arbitrary number of symbols on the right-hand-side, the production rules are specified in the string as follows. The first three symbols specify the left-hand-side of a rule. Now there is another kind of punctuation: each of the sequences {BB, BC, BD, CB, CC, CD, DB, DC, DD} indicate the end of the current rule; the right-hand-side of the rule consists of all of the symbols up to, but not including, the next such punctuation. The next rule is then built from the symbols following that punctuation. For example, the string

DEFDEFBCGHIGHI

contains the punctuation sequence ${\tt BC}$, and so specifies the two production rules

$$\begin{array}{l} {\rm D}{<}{\rm E}{>}{\rm F} \rightarrow {\rm DEF}, \\ {\rm G}{<}{\rm H}{>}{\rm I} \rightarrow {\rm GHI} \end{array}$$

The use of sequences of symbols as punctuation precludes their use as data; it is impossible to build a rule that explicitly rewrites to any substring containing a punctuation sequence, though it can be done indirectly.

The Fitness Function

We adjust the metabolism of the organisms based on the result of applying a fitness function to their solutions. Since L-systems are well suited to growing self-similar patterns, we use a fitness function that rewards strings with extensive repetition, in the hope that decoders well suited to the problem will emerge. The fitness function counts the number of occurrences of the symbol $\mathbb E$ in the solution, up to a maximum of 150.

Since we are looking for the evolution of evolvability, we use a fitness function that changes periodically in a structured way; if the fitness function was static, then once the population performed perfectly there would be no meaningful sense in which it could be evolvable or not. After a while we switch to rewarding for occurrences of the F symbol, then G, H, I, and back to E.

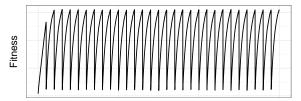

Simulations and Results

We ran simulations in order to find factors leading to the evolution of evolvability. We were also looking for the emergence of stable, self-reproducing decoders: organisms whose production rules, applied to their own axiom string, yield a description of themselves.

Since the fitness function changes periodically, the average fitness of a population over time will look like Figure 2a, increasing until the change point and then dropping to almost zero. We switch the fitness function every 100,000 fitness function evaluations. We measure the average fitness within each window of 100,000 evaluations, giving a single number measuring how effective the population was at maximizing the fitness function within that window.

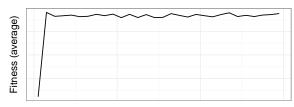

Figure 2b shows an example of the window-averaged fitness over time. Within a given window, the height of this graph gives an indication of the evolvability of the population with respect to the fitness function in that window. A positive slope would indicate the evolution of evolvability.

We compared the performance of a population of self encoders, using the context-sensitive L-system decoding mechanism, with two other methods of optimizing the fitness function. One is a simple genetic algorithm, in which there are no production rules; the genome string directly represents a solution to the fitness function. We use the genetic algorithm

Time (# fitness function evaluations)

(a) An example of average population fitness over time.

Time (# fitness function evaluations)

(b) An example of the fitness over time, averaged over each fitness function window. Within each window of 100,000 evaluations we use this single number as an indication of evolvability.

as a baseline against which we compare the performance of the other methods.

The other method used for comparison does have a set of production rules, but these are used to construct only a solution, rather than a solution and the production rules of the next generation; at each reproduction step, the genome string is copied to the offspring and mutated, the parent's production rules are applied to the genome string, and the result specifies the solution. The parent's production rules are then also copied to the offspring and mutated. We call this the *solution encoder*, since the organisms control only how they encode the solution, and the encoding of the decoder is fixed. The purpose of comparing against the solution encoder is to determine whether the self-encoding property has an effect on the evolution of evolvability.

Each simulation ran for 3,000,000 function evaluations/births. We ran each simulation forty times for each method. In the fitness plots in the following sections, the solid or dashed line shows the median fitness amongst these runs over time, and the surrounding shaded region lies between the 25th and 75th percentiles.

Simulation 1

In the first simulation, we compared a population of self encoders, solution encoders, and the genetic algorithm, each with a population size of 20×20 . Figures 3 and 4 show the results.

The solution encoder performs well. The performance profile of the self encoder population is similar to, if a little worse than, that of the genetic algorithm. The reason is that the population is quickly dominated by organisms with empty sets of production rules. The following are some example

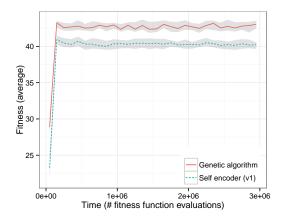

Figure 3: The window-averaged fitness of the self encoder and genetic algorithm over time in simulation 1, with a population size of 20×20 .

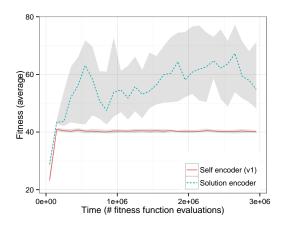

Figure 4: The window-averaged fitness of the self encoder and solution encoder over time in simulation 1, with a population size of 20×20 .

genomes from the self encoder population.

AAGGGHGGDGGGJGG AAAGEEEEEEAEEEEFE GAAJGJFJJJEJHJJJJJJ

The organisms are evolving to have AA, the punctuation that indicates the end of the production rule specification and the start of the solution, right at the start of their genome strings; they will have no production rules, nor will any of their descendants, unless mutation disrupts the punctuation.

We suspect that this happened because the initial search over production rule sets is detrimental, and so selection acts against any organism with production rules. To test this, we introduced a variation of the self encoder, in which AA only acts as punctuation if it appears in the second half of the output string. The result is to force the self encoders to have non-empty production rule sets. We call the new population

the self encoder (v2), and the original the self encoder (v1).

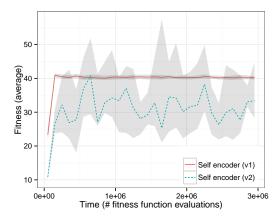

Figure 5: The window-averaged fitness of the self encoder (v1) and self encoder (v2) over time in simulation 1, with a population size of 20×20 .

The typical organism in the self encoder (v2) population has a single, long production rule in its decoder. We observed no instances of single-generation self-reproducing organisms, but we frequently found examples of two-generation reproducers, in which an organism and its 'grandchild' have the same production rules. Gestation times were low; typically, organisms went through one or two decoding steps. We found that, often, the genome explicitly contained the solution.

Figure 5 compares the performance of a population of self encoders (v1) and self encoders (v2). The population of self encoders (v2) doesn't perform especially well, but the wide inter-percentile range suggests that, sometimes, the population evolves decoders that confer evolvability.

Simulation 2

The high variance in the evolvability of the self encoder (v2) population in simulation 1 suggests that, sometimes, good sets of production rules do evolve. This motivated us to increase the population size to 20×100 for the next simulation. Since direct competition is between neighbours, the increased population size and rectangular shape has the effect of reducing the rate at which the descendants of a fitter organism spread in the population. This ought to allow multiple competing decoders to co-exist in the population at any time, allowing greater exploration over decoders before any one of them dominates the population.

Figures 6 and 7 show the results. The self encoder (v1) population is again dominated by organisms with empty sets of production rules. The self encoder (v2) performs worse than the self encoder (v1) for the first six or so fitness function windows, then performs better. This appears to show long-term adaptive evolution in the G-P map, the beneficial effect of which remains when the fitness function changes.

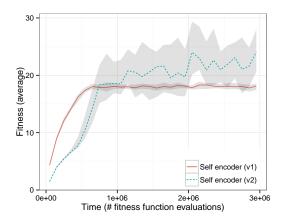

Figure 6: The window-averaged fitness of the self encoder (v1) and self encoder (v2) over time in simulation 2, with a population size of 20×100 .

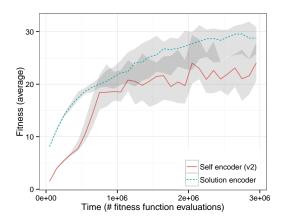

Figure 7: The window-averaged fitness of the self encoder (v2) and solution encoder over time in simulation 2, with a population size of 20×100 .

Simulation 3

In the previous two simulations, the self encoder (v2) population became quickly dominated by organisms with decoders consisting of one long production rule. The organisms are not evolving to make use of the 'end rule' punctuation. We measured the relative frequencies of the symbols in the decoded strings over a whole run as follows.

ſ	A	В	С	D	E
ſ	0.16	0.04	0.04	0.04	0.14
ſ	F	G	Н	I	J
ĺ	0.12	0.14	0.14	0.12	0.06

Symbols E-I appear frequently because they are each, in turn, rewarded for. Symbol A appears frequently because it appears in the punctuation that indicates the start of the solution, without which the solution would be empty. Symbols B, C, and D, which appear in the rule-separation punctua-

tion, appear less frequently than symbol J, which doesn't serve any purpose; they are actively selected against. To see what would happen if organisms evolved to have large sets of shorter production rules, we added a restriction: the right-hand-side of each production rule must be less than or equal to ten symbols long.

Figures 8 and 9 show the results of this simulation. Now the self encoder (v2) out-performs the self encoder (v1) almost immediately, showing the adaptive value of searching over decoders. But the self encoder (v1) population is still dominated by organisms that evolve empty sets of production rules. Without the constraint to force non-empty production rule sets, the initial detrimental effect of searching over decoders still prevents the search from ever beginning.

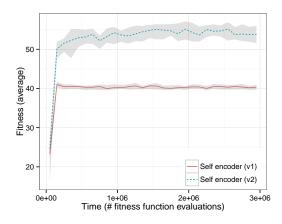

Figure 8: The window-averaged fitness of the self encoder (v1) and self encoder (v2) over time in simulation 3, with a population size of 20×20 and a limit on the size of each production rule.

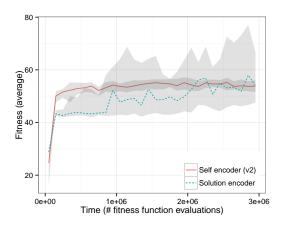

Figure 9: The window-averaged fitness of the self encoder (v2) and solution encoder over time in simulation 3, with a population size of 20×20 and a limit on the size of each production rule.

In the self encoder (v2) population, gestation times were higher than in simulation 2, with organisms typically going through four or five decoding steps. We found that, more frequently than in simulation 2, the solution wasn't contained explicitly within the genome, but was actually grown by applying the production rules. We observed a kind of 'fuzzy' reproduction, in which an organism is similar, but not identical, to its parent or grandparent. For example, the following two sets of production rules are from one organism (left) and its grandchild (right).

```
B < E > G \rightarrow AGGAGGAGGA
                                          B<E>G → AGGAGAGEGA
A < G > B \rightarrow EGAGGAGGAG
                                          A < G > B \rightarrow EGAGGAGGGA
A < G > G \rightarrow AGGAGGAGGA
                                          A < G > G \rightarrow GAGAGABEJF
\texttt{D}{<}\texttt{F}{>}\texttt{H} \to \texttt{AGGAGGAGGA}
                                          \texttt{D}{<}\texttt{F}{>}\texttt{H} \to \texttt{BEFEIFHBEF}
E < A > E \rightarrow IFHAAGGAGG
                                          E < C > C \rightarrow FDACJEGDAC
\texttt{E}{<}\texttt{G}{>}\texttt{A} \to \texttt{GGAGGAGGGH}
                                          E < G > A \rightarrow GGAGGGAGGG
F < E > B \rightarrow EABEAEBEAB
                                          E < G > G \rightarrow AGGGAGGAGA
\texttt{F}\texttt{<}\texttt{E}\texttt{>}\texttt{F}\to\texttt{EBEABEAEFE}
                                          F < E > F \rightarrow FHJDGAGEGA
\mathsf{G}{<}\mathsf{A}{>}\mathsf{G} \to \mathsf{GAGGAGGGAG}
                                          G < A > G \rightarrow EGAGGAGGGG
                                          G<E>G → AGGAGGGGAG
G < G > A \rightarrow GBEGAGGAGG
                                          G < G > A \rightarrow GGGAGAGGAG
G < G > G \rightarrow AGGJFE
                                          G < G > G \rightarrow AGGAGBEGAG
```

Conclusions and Future Work

We have described a model of reproduction, called the self encoder, in which the genome contains an encoded description of the G-P map. In this model, all variation in the offspring, including variation in the G-P map itself, is mediated by the G-P map implemented by the parent. We simulated populations of organisms whose G-P maps were context-sensitive L-systems. Our purpose was to discover whether the self-encoding property has any effect on the evolution of evolvability, as well as to find other factors that lead to the evolution of G-P maps that confer evolvability (with respect to a dynamic fitness function) on the organisms that implement them.

We also looked for the emergence of self-reproducing G-P maps. We observed a kind of 'fuzzy' reproduction, in which organisms had similar G-P maps to their grandchildren or great-grandchildren. In future work we aim to measure the degree of similarity between generations.

We found no conclusive evidence of a difference between the ability of organisms with and without the self-encoding property to evolve evolvability, nor did we rule out such a difference. We found that in the self-encoding population 'good' G-P maps failed to evolve until we added constraints to the model to push evolution towards them. However, once we added the constraints good G-P maps evolved quickly. This was to be expected, as evolvability confers a future advantage, whereas selection acts based on current fitness.

First, we found that populations became dominated by organisms whose L-systems had no production rules. Once we added the constraint that forced them to have non-empty sets of rules, in some cases the population went on to discover

G-P maps that increased evolvability. Second, increasing the population size led to the evolution of good G-P maps, since it allowed multiple G-P maps to co-exist for longer; it allowed the exploration of and selection between G-P maps. Third, we found that organisms tended to evolve to have a single long production rule. We added a constraint to force the population to evolve to have a large number of short production rules, and found that as a result the population discovered better G-P maps.

In future work we aim to study a wider range of constraints and mechanisms causing selection for good G-P maps, with an emphasis on mechanisms that are hypothesized to operate in nature.

Ecosystem memory is emergent from local-level natural selection

Because the form of an ecosystem is shaped chiefly through the selection and amplification of chance genetic and environmental events at lower levels of organisation (sensu Maynard Smith and Szathmáry (1997)), the number of evolutionary outcomes for these systems is enormous. Theoretical models of ecosystem evolution and function generally show sensitivity to initial conditions and small disturbances that result in very different behaviours for mature systems (May, 2001). These non-linearities mean that ecosystem function is historically contingent; we observe path dependency (over evolutionary timescales) as well as those non-linearities (including hysteresis) that occur over ecological timescales. For researchers seeking to understand the degree to which ecosystem properties are the result of abiotic environmental conditions and the extent to which they are emergent from self-organisation (Levin, 1998), this contingency adds an additional intricacy: some ecosystem features may be a result of residual selforganisational responses to prior environmental conditions that are no longer active.

We present a mathematical model in which an ecosystem of species, all at the same trophic level, compete for limiting resources according to Lotka-Volterra (LV) dynamics. In common with standard LV models, competition between species is modeled through interaction coefficients that summarise the extent to which species' niches overlap (Pianka, 1974). We extend this framework by allowing evolutionary pressure to affect species resource utilisation profiles, such that natural selection alters the pattern of species nicheoverlap, with the result that interaction coefficients change over evolutionary timescales. We alternately expose this system to two configurations of environmental forcing, each of which favours certain species over others (through variation in environmental carrying capacities, Figure 1). In the case where niche-space is saturated, decreases in competition with one species can only be achieved through increases in competition with another and species are under greatest selective pressure to minimise competition with those species with which they co-occur at the highest densities.

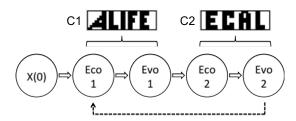

Figure 1: Schema of simulation showing key stages. An initial community of 232 species, X(0) is subjected to environmental conditions C1 (a pattern of differential carrying capacities). Ecological dynamics (Eco 1) are run until the system reaches an stable distribution of species densities (i.e. an attractor), at which point evolutionary effects are applied (Evo 1). The process is repeated for environmental conditions C2. As the distribution of carrying capacities in C1 and C2 is arbitrary, we have chosen patterns that correspond with two events that occur in alternate years.

Under these conditions, ecosystems that are exposed to multiple patterns of environmental forcing develop attractors for these configurations even when environmental forcing is lifted (Figure 2b). This property enables the system to recover these specific configurations, even from initial conditions that are ambiguous compositions of both of the historically experienced environments (Figure 2c). We find that the longer that an ecosystem remains under any configuration of forcing: i) the greater the disturbance it can withstand when forcing is removed and still return to the same composition of species; ii) the speed at which the system recovers from a disturbance increases; and iii) the longer the system can spend evolving at another attractor before the current attractor is 'forgotten'.

We recognise the presence of underlying organisational principles that enable these interesting system-level behaviours to emerge from local-level selection. We discuss how access to these principles has the potential to advance our understanding of ecosystem properties such as memory, robustness and resilience.

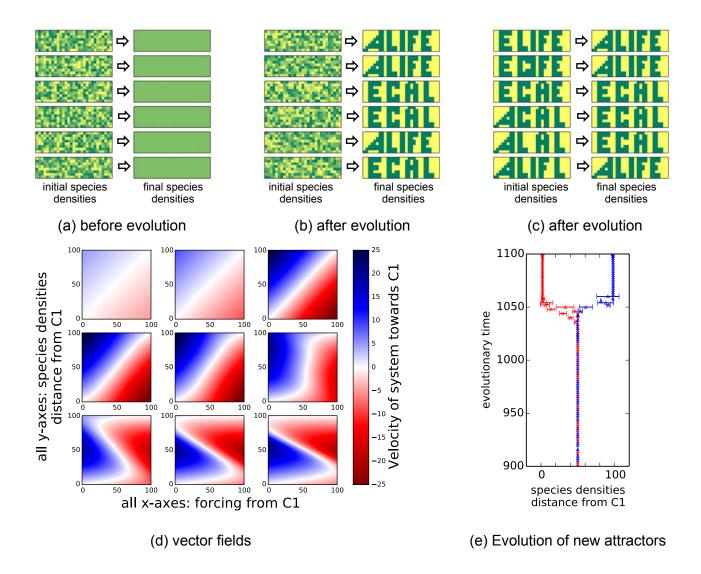

Figure 2: (a) Before the evolution of ecological interactions (and in the absence of any ecological forcing) the system has a single attractor, where all species are at the same density. After evolution of ecological interactions under alternating forcing, the system is examined again without ecological forcing. Now the system has two attractors corresponding to the exact configurations of environmental forcing it has experienced, meaning the system will return to one of these attractors from any set of random initial conditions (b) and even return to the nearest one of these attractors from initial conditions representing compositions of both the forcing patterns (c). These attractors are created as the system undergoes a fold bifurcation. The system's response to forcing is initially linear ((d): first row of panels). After an intermediate period of evolution ((d): middle row) the system's response to forcing is non-linear and the species densities develop increasing 'switch-like' convergence to the two attractors. At the final stage of system evolution ((d): last panel) ecological forcing is insufficient to move the system out its current attractor. (e) Monte Carlo analysis shows emergence of the two attractor state at around generation 1050.

Evolving biological systems: Evolutionary Pressure to Inefficiency

Dominique Chu¹ and David Barnes¹

¹School of Computing, University of Kent, CT2 7NF, Canterbury dfc@kent.ac.uk

Abstract

The evolution of quantitative details (i.e. "parameter values") of biological systems is highly under-researched. We use evolutionary algorithms to co-evolve parameters for a generic but biologically plausible topological differential equation model of nutrient uptake. In our model, evolving cells compete for a finite pool of nutrient resources. From our investigations it emerges that the choice of values is very important for the properties of the biological system. Our analysis also shows that clonal populations that are not subject to competition from other species best grow at a very slow rate. However, if there is co-evolutionary pressure, that is, if a population of clones has to compete with other cells, then the fast growth is essential, so as not to leave resources to the competitor. We find that this strategy, while favoured evolutionarily, is inefficient from an energetic point of view, that is less growth is achieved per unit of input nutrient. We conclude, that competition can lead to an evolutionary pressure towards inefficiency.

Introduction

Much is now known about biological systems at the molecular level. There are countless databases that contain gigabytes of detailed information about biochemical networks, reactions, gene regulation, protein-protein interactions and much more. As far as biochemical reaction networks are concerned, most of the available information is about structural properties of these networks, i.e. which molecules react with which molecule, which protein represses/activates which gene and so on. At the same time, very little is known about the quantitative details of these reactions, i.e. how fast reactions proceed, how strong a gene is repressed or at what rate genes are expressed.

Recently, a large scale analysis of topological data has led to important insights into the design principles of living systems. The discovery of so-called network motifs(Alon, 2007; Kashtan and Alon, 2005; Mangan and Alon, 2003), i.e. over-represented local connectivity patterns of gene regulatory networks is but one example. These motifs were found to be not only statistically over-represented but also functionally significant(Alon, 2006). While much research effort has been expended to understand the significance of

these topological features, very little research has been done to understand quantitative details of biochemical reaction networks(Chu, 2013).

One of the conditions for being able to gain insight into the topological design principles of biological systems was the wealth of empirical available about them. Since there is not a comparable amount of information available about the parameter values of biochemical networks, it is only natural that much less is known about the quantitative design principles of natural systems. At the same time, it is likely that the values of parameters of biological systems contain very much biologically valuable information. They are a product of natural evolution and as such have to be assumed to reflect the adaptive pressures to which the system has been exposed and as such encode valuable biological information.

In order to understand the principles that guide the evolution of quantitative parameter values, it is not necessary to know the actual values of biological systems. Instead, a different approach based on synthetic evolution using evolutionary algorithms can be used. In this article we will take this approach. To do this we focus on a generic topological model of nutrient uptake, i.e. a model that only contains the structure of the biochemical reactions, but not their numerical parameters. We then use evolutionary algorithms to evolve parameters for specific conditions. Comparisons of a large number of runs will then enable us to draw some conclusions as to how parameters evolve. The hope is that these conclusions are valid beyond the specifics of the particular model we have chosen and provide insight about natural biological systems as well.

Our model does not describe any specific biological system, but it is a biologically plausible generic representation of nutrient uptake in bacteria and contains topological features that are widely used by bacteria. An important way for bacteria to take up nutrient is by importing nutrient molecules through specialised openings at the cell surface—so called *porins*. These porins are proteins and they tend to be specific to a particular nutrient type. So, a porin for one nutrient cannot be used to take up a different type of nutrient. In bacteria, these porins whose production requires energy

are only expressed by the cell when the relevant nutrient is actually present in the environment. A typical way for the cell to achieve this is to use the nutrient as an activator for the expression of the porin. Once imported into the cell the nutrient stimulates the expression of the gene coding for the porin (indeed, often it represses the repression of the gene, which amounts to stimulation). This very general scheme of porin activation is reflected in our model.

A typical feature of bacterial uptake system is that expression is demand driven and porins are only produced when they are needed. The evolutionary rationale for this is that gene expression requires resources that could be invested otherwise, for example to fuel growth. Moreover, there is finite space on the cell surface which limits the number of porins that can be expressed at any one time. It is also commonly observed that over- or under-expressing a gene often decreases the growth of the mutant strains. So, apparently, for many proteins there is an optimal rate of porin expression. At the same time, evolution has the ability to tune the rate of some biochemical reactions, including the rate of gene expression. It is therefore likely that the particular rates of gene expression and that of other bio-chemical reactions are fine-tuned by evolution.

This motivates the research question to be addressed in this contribution: How do the parameters of generic bacterial uptake systems depend on the adaptive pressures that led to their emergence. Moreover, given a set of adaptive pressures, is it possible to predict the parameters, or vice versa, given a set of parameters, is it possible to understand what adaptive pressures led to them? Finally, can the results obtained from the generic biologically plausible model provide any insight that is relevant for the real world.

To address these questions, we performed two types of artificial evolution experiments. Firstly, we evolved parameters (i.e. "solutions") on their own. We found that this results in uptake mechanisms that could turn most of the nutrient on offer into growth using a very low number of porins resulting in slow nutrient uptake and growth. We found this to be the most efficient mode of growth because it allows the cell to channel most nutrient into growth while minimising the amount of energy spent on the uptake mechanisms. In a further set of experiments we then evolved new solutions in competition with a previously evolved one.

The solutions obtained from these co-evolutions were different from the solutions evolved without competition. Rather than taking up nutrients slowly with a low number of porins, they evolved towards increasingly rapid uptake of nutrient (although not necessarily rapid growth). While this allowed them to grow fast it also means, as we will discuss below, that they grow inefficiently. Specifically, we found a clear trend that co-evolved solutions are less efficient than the original solutions that evolved without a competitor. However, within the chain of evolved solutions there was no clear further trend toward inefficiency. Hence, rather

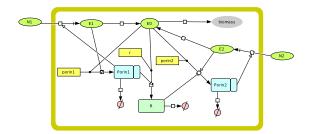

Figure 1: A schematic representation of the model.

than getting more efficient by competition, we found that coevolution leads to less efficient solutions, which is a counterintuitive at first. We will argue below that this pattern towards inefficiency is universal, in the sense that it does not depend on the specifics of the particular model, but would be true for a large class of nutrient uptake systems, including those of real organisms.

Furthermore, in our simulations we presented the simulated cells with two different types of nutrients of differing quality. We also added a structural motif into the model that would allow the cells to suppress take-up of the less valuable nutrient 2 in favour of the other. Indeed, we observed the evolution of the suppression of nutrient 2 uptake. However, surprisingly to us, the solutions did not use the motif offered, but instead came up with a different way of regulating the uptake of the less efficient nutrient.

The basic model

We present here a generic model of a bacterial uptake/metabolic system (see figure 1). The idea is that there are two sources of nutrients N_1 and N_2 . Uptake of these sources of nutrients requires specific porins, namely P_1 and P_2 respectively. Once taken up into the cell the nutrient becomes an internal source of energy $(E_1$ and $E_2)$ which can be converted into actual energy (or ATP), which we denote by E_0 . We assume that the uptake and conversion of nutrient follows Hill kinetics(Chu et al., 2011). The internal energy is converted either into porins (i.e. porin 1 and porin 2 abbreviated as P_1 , P_2) or into biomass (bm) which represents the results of bacterial growth.

We only determined the topology of this model which is designed such that the expression of porin 1 and 2 is activated by the presence of nutrient 1 and 2 within the cell (i.e. E_1 and E_2 respectively). The model topology does not by itself specify how strong this activation is. The strength of the activation depends on the parametrisation, which needs to be evolved. Indeed, there are many parameters that would effectively turn off the activation. The same is true for all other regulatory functions in the model.

An important feature of the model is that the expression of nutrient and the production of biomass require energy. Hence, the (*a priori* unspecified) parameter values for the expression rates of porins and the growth rate decide to what extent the resources (i.e. nutrient) is used to fuel growth and to what extent it is used to maintain the cellular uptake machine, i.e. how much is allocated to porin production.

It appears that there is an optimal allocation of resource to growth and the uptake mechanism. If the cell allocates no energy to uptake but all to growth, it will not be able to use any of the nutrients and hence it will not grow at all. On the other hand, if the cell allocates all of its nutrients into uptake, but none into growth, then it will be rich in nutrients, but never grow and hence never divide. In-between these two extremes there is one (or possibly several) optimal allocation. While it is clear from this argument that such an optimum exists, we do not know where it is and what it depends on.

Another important feature of the model is that the total number of porins in the system is limited. Porins in bacteria are located at the cell surface. They build openings there and selectively let molecules in and out of the cell. In real cells there is limited space on the surface to accommodate porins. This limitation is represented in our model by the term L (see below). It is a repressing term that reduces the expression of porins 1 and 2 as a (Hill-repressor) function of the sum of the concentration of both.

Finally, the model also features a repressor motif. The molecule R is expressed when there is porin 1 available in the cell and its sole purpose in the model is to repress the expression of porin 2. This sort of regulatory motif whereby a repressor is activated by some part of the system and represses another part of the system is commonly found in gene regulatory networks. The idea of introducing this motif is to enable the cell to evolve a repression mechanism for nutrient 2 when the (better) nutrient 1 is available.

The topology of the model can be summarised by these chemical equations:

$$N_{i} \rightarrow \epsilon_{P_{i}}E_{i}, k_{N_{i}}p_{i}\frac{N_{i}}{N_{i}+K_{N_{i}}}$$

$$E_{i} \rightarrow E_{0}, k_{E_{i}}E_{i}$$

$$P_{1}+E_{0} \rightarrow P_{1}, k_{P_{1}}\frac{E_{1}^{h_{P_{1}}}}{E_{1}^{h_{P_{1}}}+K_{P_{1}}^{h_{P_{1}}}}E_{0}L$$

$$P_{2}+E_{0} \rightarrow P_{2}, k_{P_{2}}\frac{E_{2}^{h_{P_{2}}}}{E_{2}^{h_{P_{2}}}+K_{P_{2}}^{h_{P_{2}}}}\frac{K_{R}^{h_{R}}}{R^{h_{R}}+K_{R}^{h_{R}}}E_{0}L$$

$$P_{0} \rightarrow k_{P_{0}}\frac{P_{i}}{P_{i}+K_{P_{i}}}$$

$$r+E_{0} \rightarrow R, k_{R}E_{0}\frac{E_{1}}{E_{1}+K_{R}}$$

$$\{P_{i}, E_{i}, R\} \rightarrow \emptyset, d_{\{P_{i}, E_{i}\}}$$

$$E_{0} \rightarrow bm, k_{C} \qquad (1)$$

where L is the space-limit which represents the fact that

there is limited space at the surface of cells to accommodate porins, given by

$$\frac{K_L}{(P_1 + P_2) + K_L}$$

The quality factor ϵ_{P_i} determines the quality of a nutrient and we set it to 1 for P_1 and 0.5 for P_2 . This means that one unit of nutrient 2 gives only 1/2 unit of biomass. Uptake and gene expression are assumed to follow Hill kinetics. While this is an approximation, in reality it has been found that Hill kinetics is a good description of the reactions described here. It is also widely used to model them and is a fairly simple approach. In all simulations reported here we keep the Hill exponent fixed at a value of 2, which is biologically plausible.

Evolving the system

In this article we evolve parameters for the topological model described by equation 1. Concretely this means that we evolve values for the kinetic parameters determining the system, including the Hill-constants (i.e. K_{N_i} and dynamic constants such as k_{P_i} . Note that we do not evolve the decay rate d which we keep fixed at 0.1, the Hill exponents (i.e. $h_x=2$), the relative value of ϵ_{P_i} (which we keep fixed at 1 and 0.5 respectively) and K_L which determines how much space there is for the porins in the cell. This latter parameter we set to 1. All other parameters are evolved and we allow them to take values between 0 and 15. In all simulations reported here the model is implemented as a system of differential equations. As a solver we use the general purpose numeric differential equation solver of the Maple computer algebra system version 16 for Linux.

The model was implemented as a co-evolutionary system, that is we have two different solutions compete for the same nutrient pool of N_i . This represents two different species of bacteria co-existing in the same environment. In practice this means that we used two sets of differential equations with two sets of the variables E_i , P_i , R, bm representing two different cell-types. Each set had their own kinetic parameters, yet their dynamics depended on one another via the shared nutrient pool. Of the two competing solutions, we ever only evolved one of those solutions, while keeping the other one fixed. Initially, we use as the fixed solution an "unfit standard solution" with all parameters set to 1. This solution supports no growth beyond the start-up allocation which is equivalent to 1 unit of biomass. Co-evolution is achieved by using previously evolved solutions as fixed solutions (i.e. "incumbents") in further evolutionary runs. In all simulations we set as the initial condition all variables to zero except for $P_i = 0.001, E_0 = 1$. This means that any solution can support a maximum of 1 unit of biomass even if it does not take up a single unit of nutrient.

During each evolutionary run only one of the solutions is evolved, while the other one is kept fixed at user-defined parameters. Co-evolution was achieved in a sequential manner, that is, one solution was evolved against a fixed solution. The evolved solution was then subsequently used as the fixed incumbent in a further evolutionary run. Co-evolutionary chains were obtained as follows;

- Evolve a first solution against an un-evolved base solution (all parameters set to 1).
- 2. Once the first solution is obtained, evolve a second solution against the first solution (which is kept fixed).
- 3. Create a third solution by evolving against the second solution (which is now also kept fixed).
- 4. Continue in this manner until no more solutions evolve.

To evolve the system we used a genetic algorithm with elitism. Individual solutions were represented as an array of real numbers in the range [0,15]. The population size was set to 50. The initial population consisted of random parameters within the range [0,15] sampled from a uniform distribution. As a fitness function we chose the biomass after 500 units of time. We found that 500 time units was large compared to the transient periods of the system, i.e. increasing this time did not change the results of the evolution.

As a selection algorithm we chose a fitness proportional selection. However, in every generation the best solution and a mutated version of it was allowed to proceed to the next population. The mutation and crossover rate was set to 0.8. Mutation was done by changing a random parameter by up to ten percent of its current value. If a mutation resulted in a value lower than 0.00001 or greater than 15 then the parameter was set to 0.00001 and 15 respectively. The amount of available nutrient was set to 10 for both nutrient types. The GA was implemented in Perl, but the fitness function was evaluated using Maple. Both the relevant Maple script and the Perl source code are available from the authors upon request.

We performed two different types of experiments. Firstly, we performed a simple evolution without competition (i.e. with the standard unit solution as competitor). Subsequently, we used the results of those evolutionary simulations to initiate a co-evolutionary chain, as described above. In practice we found that after a number of iterations no more fit solutions were found, in the sense that the total biomass produced for the evolving solution did not substantially exceed 1, i.e. evolution could not find solutions to outperform the incumbent. In this situation it was helpful to evolve a new solution by seeding the new evolutionary solution with the incumbent parameters, rather than starting from a random solution. However, even in this case, the co-evolutionary potential was limited.

Individual evolutionary runs were stopped either after 5000 generations or when a plateau of high fitness with no apparent further increases over time was reached, whatever

happened first. The presence of such plateaus was determined by visual inspection. In practice, it turned out to be a clear-cut case. A typical evolution would show rapid increases of the fitness at first, followed by fitness stagnation.

Results

Unconstrained evolution

We evolved a number of solutions without competitor. Figure 2 illustrates three typical results obtained from unconstrained evolution. It shows the amount of biomass over time obtained by simulating in Maple the best solution of the final population in the GA. It is part of the set-up that there is a limited amount of nutrient of 20 units divided across two types of nutrients. Since the second nutrient gives only half the growth of the first, at best the available resource can be converted into a biomass of 15 units under ideal conditions; the solutions also get a start-up energy equivalent to 1 biomass. Hence, in total the maximum they can reach is 16 biomass units.

It is apparent from figure 2 that most solutions evolved come close to the maximum attainable biomass, although there is some variation. Occasionally, we have also observed that solutions got stuck on a local minimum and did not discover the second nutrient source. This resulted in cells that would not take up any of the nutrient 2 and achieve only a level of about 10 units of biomass (data not shown). This indicates that the solutions were able to channel most nutrients into growth rather than using them for enzyme production. This high level of conversion was made possible by a very low assumed degradation rate of enzymes that allowed the solutions to grow at a slow rate.

The figure shows that the time required for achieving the maximal growth varies somewhat from solution to solution. The three example solution shown in figure 2 are representative for the range observed in all unconstrained evolutionary runs, Generally, we observed that these evolved solutions take up nutrient over a time period of 20 to 150 time units. There is a wide variation between the solutions that we obtained

Co-evolution

Co-evolution changes the nature of the solution obtained in very specific ways. The system as a whole offers a finite amount of resources and both solutions need to compete for the same two pots of nutrients. Hence, competition is not a zero sum game.

At the beginning of a co-evolutionary run the competitor will have random parameters and not be able to compete well against the incumbent. However, as new solutions are discovered the competitor evolves to outperform the incumbent. One way to do this is to consume the available nutrients faster than the incumbent. Ideally, the new solution has used up all of the nutrients before the incumbent can

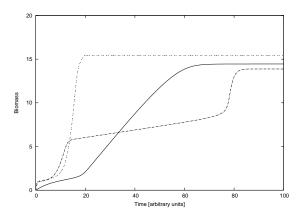

Figure 2: Three solutions of simple evolutions where the competitor is the maximally unfit solution.

do this preventing the latter from growing. Indeed, throughout all co-evolutionary runs we performed, this speed strategy emerged as one important way for solutions to undermine their competitors' abilities to grow. Co-evolution led to a sequence of increasingly fast solutions until a limit was reached and no more increases were possible. Note, however, that increased speed does not necessarily mean an increased growth-rate. Indeed, we observed a number of cases where growth was slower (i.e. occurred later) in the new competitor than in the incumbent but its nutrient uptake was still faster.

Figure 3 shows a typical co-evolutionary interaction. The first solution, which has been evolved against the unfit set of parameters, takes up nutrients slowly. This particular solution requires more than 100 time units to reach the final biomass. In contrast, the second solution is much faster and reaches its final biomass within 15 time units. Interestingly, the third solution, which is evolved against the second one, grows slower. Yet, a closer inspection shows that, while it produces biomass slower, its nutrient uptake is faster than that of the second solution. Hence, it leaves no nutrient to the second.

In all evolutionary experiments we performed we never found a case where a solution evolved to co-exist with its competitors, in the sense that *both* the incumbent and the competitor were able to take-up nutrient and grow. Instead, in all cases we considered, one solution came to dominate the other. However, there are cases where we observed the dominated solution to have some minimal growth, i.e. less than 1 biomass unit above the start-up energy.

Connected to this minimal growth of the dominated competitor we observed an interesting phenomenon. Figure 4 shows two simulations of a solution that we had obtained as a third solution during one of our co-evolutionary chains. Note that the graph does *not* show the evolution experiment, but an evaluation of the solution obtained from one of the

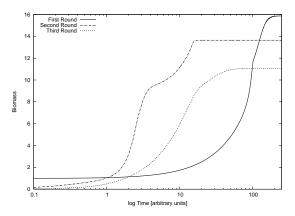

Figure 3: Three co-evolutionary solutions. The three curves show the growth of the solutions as a function of time. The curve labelled "First" is the original solution evolved against unfit parameters. The line "Second Round" was evolved in competition with the first and similarly the "Third Round" was evolved against the second. Time is shown in log scale to improve readability.

evolution experiments. The difference between the two runs in figure 4 is the competitor with which the evolved third solution competes. In one curve it is the standard unfit solution (which does not consume any nutrient) and in the other it is the second solution, i.e. the solution against which the third solution was evolved. In this particular case the second solution takes up a small amount of nutrient when competing against the third solution and grows roughly by 0.6 (data not shown) above its initial endowment. On the other hand the unfit solution, where all parameters are set to 1, does not take up any nutrient in competition with the third solution. Hence, one would assume that the growth of the third solution when competing with the second is lower than when competing with the standard solution. However, in reality, the third solution leads to a *higher* biomass in combination with the second solution than against the standard unfit solution. This is shown in figure 4. Increased nutrient uptake requires a higher level of investment into the metabolic machinery compared to the

Upon closer inspection this effect can be related to the usage of the second (less efficient) nutrient. In competition with the standard unfit solution the third solution does not use up all of the less efficient nutrient, but in competition with the second solution it does. This hints at the explanation for the observed effect. When competing with the standard unfit parameters the third solution has more nutrient 1 available. This additional nutrient leads to a higher production of porin 1 than when competing with the second solution. Note that there is a limit to the total number of porins for nutrient 1 and 2. Hence, if there is more porin for nutrient 1 produced then this means that less porin for

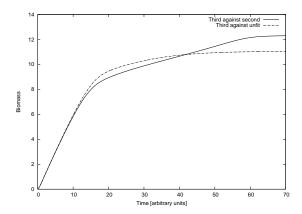

Figure 4: Comparing the third solution when evaluated against the unfit solution and against the second solution. Surprisingly, it does better against the (evolved) second solution than it does against the unfit standard solution.

nutrient 2 can be produced. Indeed, in the competition with the standard solution the porin for nutrient 2 is lower and tends to zero before all of the nutrient 2 can be taken up. In competition with solution two, on the other hand, the overall amount of porin 1 is lower which allows more porin 2 to be produced. The effect of this is that sufficient amounts of the porin can be produced to take up all of the available nutrient 2. Altogether, this leads to higher growth.

Based on this, one would expect that less biomass is produced by solution three in competition with the second solution than with the unfit parameters when the limit on the total number of porins is removed. To check this, we performed simulations where we removed the limitation (i.e. removed the factor L from equation 1). A comparison of solution three under these two different conditions then shows that indeed it develops more biomass when paired with the unfit solution than when with solution two (data not shown).

A comment on switching

In real bacteria there is a phenomenon called "diauxic growth." When bacteria are presented with two nutrient sources of different quality then they take up the good quality source first. Only when this one is exhausted will they take up the secondary source. From an adaptation point of view it is quite straightforward to make sense of this. Those cells that take up the good quality nutrient faster will be able to produce more offspring (because they have the better quality nutrient) and hence out-compete the others while at the same time leave less for their competitors. By the same reasoning, we expected to observe the emergence of diauxic growth in our artificial evolution experiments. Hence, we included a simplified mechanism to allow cells to suppress production of porin 2 when porin 1 is present in the cell. We specified that the regulator R has a suppressing effect on the

expression of porin 2, but requires porin 1 to be expressed itself. Given the right parameters, it should then be possible for diauxic growth to emerge.

In our simulations we found that the evolved solutions universally favoured porin 1 over porin 2, but they did not use a switching mechanism based on the regulator R. Instead the cells evolved other mechanisms to ensure that nutrient 1 is always taken up before nutrient 2.

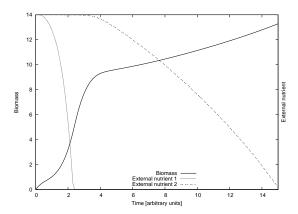

Figure 5: A second round solution and the amount of external nutrient available. Nutrient one is exhausted after around 2.5 time units. Only then the consumption of nutrient 2 starts. The control mechanism relies on limited space for porins. See main text for details.

We observed a small number of solutions that did not take up nutrient 2 at all. Amongst those solutions that did take up nutrient 2 a subset did not have any apparent regulation mechanisms, but simply took up nutrient 2 at a slow rate compared to nutrient 1, i.e. produced porin 2 at a low rate. This is only a mechanism in the most trivial sense. A more advanced, true mechanisms that frequently evolved was based on the limit on the total number of porins via the factor L in equation 1. The idea is as follows: If the porins for nutrient 1 are expressed at a higher rate than those for porin 2, then this leads to a higher rate of uptake of nutrient 1, further stimulating expression of porin 1. Since there is limited space, once a certain amount of porin is expressed, further expression of any type of porin is suppressed. Altogether, this allows porin 1 to increase its advantage and to crowd out porin 2 which is expressed at a low rate only. Yet, once nutrient 1 runs out, porin 1 is no longer produced and then porin 2 can be expressed.

While this mechanism effectively repressed porin 2, it limits by design the speed with which porin 2 can be expressed and hence it limits the uptake speed of nutrient 2. The ideal scenario for a bacterial cell would be to take up nutrient 1 rapidly, then switch and take up nutrient 2 rapidly. However, the simple regulatory mechanism via L relies on the production of porin 2 to be slower than that of porin 1

and therefore does not allow efficient repression of nutrient 2 uptake while nutrient 1 is still present *and* rapid uptake of nutrient 2.

This begs the question as to why the system does not accept the repressor R for the regulation of nutrient 2. The repression topology we used is a common gene regulatory motif in biology to control the expression of genes. Yet still, in none of the simulations that we performed it was used to regulate the expression of porin 2. We suspect that this simple regulatory motif is not effective in the regulation of porin expression. We conjecture that the underlying reason for the failure to evolve has to do with the difficulty of removing the repressor once nutrient 1 has run out. Further investigations are required to understand why this regulatory system is not effective.

The effects of competition

From the above analysis of the solutions it becomes clear that co-evolutionary pressure changes the nature of the solutions. The first solution, that is evolved against an unfit competitor tends to take up nutrient over a long time. Subsequent co-evolved solutions tend to take up nutrients, especially nutrient 1, over a much shorter time. The question is now why in the absence of competition solutions tend to evolve towards slow uptake. One possible explanation could be that there simply are more solutions (i.e. combinations of parameters) that take up nutrient slowly than there are solutions that take them up fast. Hence, in the absence of co-evolutionary pressure, evolution is more likely to discover slow solutions than fast ones.

Another interpretation, that does not necessarily preclude the first explanation, is that there is a functional significance to the slow speed with which nutrient is taken up. To understand whether this is the case, we considered the growth efficiency of solutions. To do this we defined a simple measure of efficiency given by the biomass divided by the total nutrient usage. According to this measure, a solution is more efficient if it requires less nutrient to grow to a given size.

In order to gain an insight into the nature of the solution we plotted the efficiency over time; see figure 6. A clear pattern emerged. The first solution that evolved against the unfit standard solution was always more efficient than subsequent solutions. For subsequent solutions, however, there is no clear trend towards further inefficiency. So, the fourth solution may or may not be less efficient than the third solution from the same co-evolutionary chain. Figure 6 shows the efficiency of three consecutively evolved solutions as an example.

There are again two ways to interpret this finding. One could assume that this trend towards inefficiency is merely an artefact of the particular modelling choices made, or that it is a more general phenomenon that is relevant for a large class of systems including real systems. We believe the latter is the case. Within our model, nutrient can only be converted

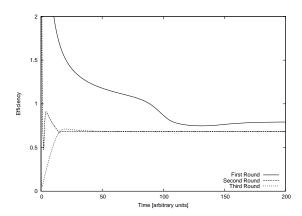

Figure 6: Comparing the efficiency of solutions during subsequent rounds. Efficiency is the amount of growth achieved for each unit of nutrient consumed.

into either biomass or into porins. The latter are necessary in order to take up nutrient. As long as there is no time-constraint on the system, it is sufficient for solutions to produce a small number of porins. It will take a long time to absorb all the available nutrient, but the investment into the metabolic machinery is low, so altogether the cell can grow efficiently. The major limiting factor here is the decay of nutrient which requires a certain production rate of porins to replace lost ones and keep the uptake stream constant. Up to that limit, slow growth is more efficient.

However, if a cell needs to compete with another one for resources, fast uptake is required, because otherwise the competitor takes up all the nutrient and nothing is left for the cell. Hence, competing cells need to take up nutrient rapidly. This is, however, inefficient. Uptake can only be achieved by a large number of porins concentrated into a small amount of time which entails a corresponding energy investment. Once the nutrient is used up, the porins no longer fulfil a function, and there is no return on their investment. Altogether, this results in an inefficient use of resources. Hence, fast nutrient uptake is inefficient independently of the specifics of the model assumptions, simply because it requires diversion of resources into porins.

Discussion and Conclusion

The current model makes a number of assumptions and simplifications. For example, the "infinite population" assumption implicit in the use of differential equations is of limited relevance for biological systems which are known to exhibit substantial noise at the molecular level. A deeper analysis of the system presented here would have to take into account stochastic fluctuations originating from the discrete nature of biochemistry. Yet, simulating such discrete systems is much more difficult than solving differential equations. Hence, for a first analysis differential equations provide a good trade-

off between feasibility and accuracy.

By using our model we found that taking up nutrients slowly is most efficient, but not necessarily the best strategy. Yet, in the absence of competitors the slowest possible growth is the most efficient one. In the hypothetical case of a continuous system with no protein breakdown an infinitely slow take-up rate corresponding to an infinitely slow expression rate of porin would be ideal. In more realistic models that include decay of components, there is an optimal rate of porin creation rate which depends on the rate of porin breakdown. The conclusion is that a group of clonal cells does best when growing very slowly, because then it expends the least amount of energy on maintaining the uptake machine. Only in competition with other cells will faster uptake rates be beneficial.

Not included in the above picture is the cost and the speed of computation. If we allow dynamically changing environments in the model then the picture changes. Environmental changes need to be sensed by the cell which then has to make internal adjustments based on the sensed changes. In the simplest case this is simply the presence and absence of nutrients. It can be shown that the speed with which these adjustment can be made depends directly on the breakdown rate and the speed of uptake. It has been shown recently(Chu et al., 2011) that slow uptake entails a limited ability to adjust to external conditions. On the other hand, faster uptake and growth is required to "compute" changes in the external environment effectively. Doing so comes at a cost in terms of additional nutrient that needs to be expended. Moreover, a hypothetical cell with no breakdown of components is not able to switch to a new state, simply because it is not able to forget its previous state. Say, at some point there are only porins of the first type in the system and these porins occupy all of the available surface, so that no more porins can be created. If then the nutrient of the first type is used up, the cell cannot express any other porins. As such it would miss out on growth opportunities. Similarly, if it can break down porins only slowly, then it will only be able to react slowly to changes in the environment. The conclusion from this is that extremely slow growth is only realistic for populations that live in constant environments that do not require any regulation.

So, in many ways the assumptions that we made in this contribution are somewhat unrealistic with respect to real biological system. Yet still, we think that the conclusions we reached are relevant. While ultra-slow speed will not be achievable in real systems, it is still likely the case that slower growing cells would be more efficient that faster growing ones simply because they will have lower rates of resource wastage. Yet, when in competition with other cells, then the slowest growth rate is no longer feasible and the cell has to invest a high amount of resource for growth. While the details of the evolutionary dynamics will be more complicated in real cells, and the particular trade-offs will be

more involved, the underlying fact that competition requires fast growth and that fast growth is inefficient is likely of very wide general applicability and relevant for our artificial cells and real biological cells alike.

Biological systems are commonly thought of as being optimal. The reasoning is that intense competition between cells will drive biosystems over time to fine-tune their internal processes to a point where resource usage and allocation is most "efficient." There are a number of well known problems of this optimality assumption. The best known one is that in evolving systems non-optimal, even slightly detrimental traits may piggy-back on advantageous traits and establish themselves in that way. Or, even in very simple fitness landscapes, constant mutational pressure will push the population away from any theoretical optimum generating a *quasi-species*(Eigen and Schuster, 1979). As a result of these and other similar effects biological systems cannot be assumed to be tuned perfectly to an optimum.

Our experiments show an additional biological driver towards inefficiency based on competitive co-evolution. Our results contradict the intuition that competition leads to efficiency. Under some circumstances biological systems are driven away from their most optimal mode of operation. One can now speculate whether or not the same effect applies in other competitive systems, such as in economics where it is routinely argued that competition to the most efficient allocation/use of resources. At least with respect to bacterial growth, our experiments seem to indicate that this is not necessarily so, but competition could lead to less efficient solutions rather than more efficient ones.

Artificial Evolutionary Ecosystems

Evolution of animats following a moving target in an artificial ecosystem

Abstract

Many biological animals, even microscopically small, are able to track moving sources of food. In this paper, we investigate the emergence of such behavior in artificial animals (animats) in a 2-dimensional simulated liquid environment. These "predators" are controlled by evolving artificial gene regulatory networks encoded in linear genomes. The fate of the predators is determined only by their ability to gather food and reproduce—no subjective function is used to select the best individuals. Food is delivered to the environment by mobile animats who are not evolved ("prey"). Our results show promise for evolving more complex behavior relevant for nanorobotics, swarm robotics, and research on the evolution of simple cognitive abilities (minimal cognition).

Introduction

The ability to find resources (such as food) is common even among the simplest organisms. Even unicellular organisms, such as bacteria, are able to sense the concentration of various chemical substances (which can serve as food) in liquid environments, and move to a place where the concentration is higher. This phenomenon is called chemotaxis, and is an example of a minimally cognitive behavior (Beer, 1996).

Minimally cognitive behaviors attract considerable interest in Artificial Life, as a possible stepping stone towards more advanced cognitive skills (Wróbel, 2012). In many such experiments, artificial neuronal networks (ANNs) were used to control artificial organisms (animats; bio-inspired robots). In one such example of the state of the art approaches to evolution of simple behavior, virtual robots—resembling arthropods—searched for prey and avoided predators using vision (Palmer and Chou, 2012).

Yet, as we mentioned above, minimal cognition can be observed in biology even in unicellular organisms. One way in which single cells process information is with intracellular signaling networks (where nodes correspond to proteins, such as kinases, or small molecules, called transmitters; a state of the node—to concentration of, for example, a phosphorylated form of a protein, or concentration of a transmitter; and edges—to regulatory interactions). Such biological networks can be seen as computational devices, and

this goes also for gene regulatory networks. Here, nodes are genes and the edges are regulatory relationships (in which a gene product regulates the activity of a gene).

Artificial gene regulatory networks (aGRNs) are a model of computation inspired by such biological networks, and have been used in experiments on the evolution of directional movement in virtual mobile robots (Quick et al., 2003; Zahadat et al., 2010). The model of aGRNs we will use in this work, called GReaNs (Wróbel and Joachimczak, 2011) has been applied before for such tasks, with a genetic algorithm as a model of evolution of either unicellular animats (Joachimczak and Wróbel, 2010; Wróbel et al., 2012), or virtual soft robots (Joachimczak and Wróbel, 2012; Joachimczak et al., 2012).

Many multi-agent simulation platforms have been developed recently. BREVE (Klein, 2003) includes rigid body simulation with friction and collision detection. It proved to be useful for simulation of flocking behavior in 3D space (Spector et al., 2003). MASON (Luke et al., 2005) has been used in diverse applications including swarm multi-agent system in continuous and discrete space. DANCE (Shapiro et al., 2005) allows to model complex physical systems including body deformation. Nonetheless, neither of these platforms allow to model diffusion with efficient storing of chemical concentrations. Therefore, we developed a simple simulated environment, where artificial organisms (animats) compete for limited resources, reproducing only when they accumulate enough of them internally.

We used this platform in our recent work (Erdei et al., 2012, 2013) where we analyzed the evolution of chemotaxis. In this previously published work, we did not use a genetic algorithm—we believe that it is an imperfect model of a biological evolution, since it requires a subjective function to evaluate fitness, an emergent property in biology. Nonetheless, when we considered evolution of behavior of animats that could prey on other animats (Erdei et al., 2013), the results were somewhat disappointing. Although the prey produced a diffusing chemical, the predators failed to evolve the ability to use the gradient of this chemical to track the prey. Rather, the predators searched for immobile food

(from which another chemical diffused), and then waited for the prey attracted by food.

In the present work we analyze if tracking of mobile prey can evolve in our artificial life platform. As previously, the animats are controlled by evolving aGRNs (using GReaNs). The task considered here—tracking a movable resource—corresponds to following a leader in swarm robotics, or chasing prey by a predator in biology. Only the predators ("followers"), however, will be evolved—the movable resource will move randomly in the experiments we will describe further on, after providing a brief recapitulation of GReaNs in the next section.

Artificial environment with diffusible substances

The model of an artificial liquid environment we will describe is an extension of the model we presented previously (Erdei et al., 2012, 2013). The model allows to simulate diffusion of substances, and movement of artificial organisms (animats) in 2-dimensional environment. The environment has no boundaries (i.e., it is a two-dimensional torus)—an animat which crosses the left border appears on the right side. While organisms occupy real-valued positions, and concentration of a substance (which can serve as food or scent) is modeled as a function of real-valued position, the concentration is stored in the software in a space-discrete data structure (quadtree; Finkel and Bentley, 1974).

This structure divides space into squares of various sizes; each square corresponds to a tree node, with the square representing the whole space at the root. Each square can be divided into 4 smaller squares (when the concentration or its gradient is high), of equal size. Thus each node can have 4 children. The leaves store the information about concentration of a substance used for modeling diffusion of providing the actual concentration to the animats (at real-valued positions, with bilinear interpolation (Gribbon and Bailey, 2004); the concentrations for squares' vertices, and centers of vertices in some situations, are calculated as an average of adjacent squares' concentrations weighted by distances to squares' centers). To simplify calculation of diffusion, we imposed a rule that each square can only border on a square of the same size, a square 4 times larger in area, or a square 4 times smaller in area (see Fig. 1).

A quadtree is a compromise, in terms efficiency and precision, between dense and sparse grids, because during simulation the squares are divided (approximating a dense grid) where the concentration (or the concentration gradient) of a substance is high. Also, the squares are divided to the smallest possible (1 square length unit in size) where animats are and where substances are released. Elsewhere, the squares remain large. The concentration of each substance is modeled separately using an individual quadtree structure. Then the concentration in each point inside a square is calculated as a bilinear interpolation using these values calculated for

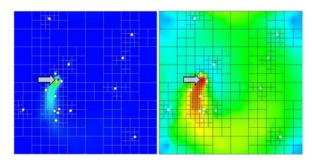

Figure 1: Modeling diffusion in 2-dimensional environment using a quadtree with continuous gradient of diffusible substances. The concentration of food is represented as hue, from blue (minimal concentration) to red (maximum concentration), scaled linearly in the left panel and logarithmically in the right one. Maximum concentration is around the prey (violet circles indicated by arrows in both panels). The predators (white circles) sense interpolated concentration values at their exact locations.

vertices.

Diffusion of substances between two adjacent squares follows the Fick's law:

$$\Delta P = \frac{c \cdot d}{D} \cdot (S_2 - S_1) \cdot \Delta t , \qquad (1)$$

where ΔP is the change in the amount of substance (by which the concentration will increase (decrease) in square 1 and decrease (increase) in square 2 if the current concentration is greater (lower) in square 2), c is the coefficient of diffusion (0.1 in the experiments described here), d is the length of the common edge, D is the distance between the centers of the squares, S_1 and S_2 are the current concentrations in both squares and Δt is the duration of the simulation step. Since each square stores concentration (not the total amount), the concentration in square X is changed by $\Delta S = \frac{\Delta P}{Ax}$ where A_x is the area of square X. At every time step, substances not only diffuse, but also degrade exponentially

$$S(t_0 + \Delta t) = S(t_0) \cdot g^{\Delta t} , \qquad (2)$$

where S(x) is the concentration of the substance in given square in time x, Δt is the duration of the simulation step, g is the degradation coefficient (in the experiments described here, 0.98 or 0.97), and t_0 is the previous moment of time.

Unicellular artificial organisms (animats) controlled by aGRNs

Animats are circular, and all are 1 length unit in diameter. Each is one cell with two flagella (Fig. 2), which work like engines (i.e., generating thrust). Flagella's activations are continuous (a value between 0 and 1) so an animat can move slower or faster depending on its strategy. When both flagella are fully activated, an animat accelerates by $\frac{1du}{(\Delta t)^2}$,

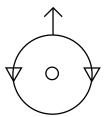

Figure 2: A unicellular animat with one sensor (circle) and two actuators ("flagella"; triangles). An arrow indicates the direction of movement when both actuators are activated equally.

where 1du is one distance unit, and Δt is the duration of the simulation step. When one flagellum is fully activated and the other is not activated at all, an animat accelerates its rotation by $\frac{1rad}{(\Delta t)^2}$. An animat experiences linear and angular friction which causes linear and angular drag proportional to its velocity squared. If animats collide, they bounce away from each other (in Erdei et al., 2012, 2013, collisions were not modeled).

There are two kinds of animats. One kind—the "prey"—have hand-written controllers which make them move in random trajectories. Prey do not eat or gather any substances, spend energy, die, nor reproduce. They deliver food to the environment (1 unit of food in each time step) that serves two purposes: it can be sensed by the second type of animats ("predators"), which also use it as a source of energy. In other words, prey are mobile food sources for the predators. The goal of our evolutionary experiments was to evolve predators which can follow the prey. We designed the experiments so that the only efficient way to obtain energy, necessary for reproduction, is to follow the prey. Using terminology taken from swarm robotics, the goal is to evolve animats that can "follow a leader".

In contrast to our previous work on controlling unicellular animats with aGRNs (Erdei et al., 2012, 2013), where animats had two sensors on two sides of the cells, predators in the present paper have each only one sensor for food. The sensor senses the local food concentration at the location which correspond to the cell center (Fig. 2).

A predator is controlled by an aGRN encoded in a linear genome. The model we use, called GReaNs, has been described elsewhere (e.g., Joachimczak and Wróbel 2008), and has been previously used to evolve controllers of animats (Joachimczak and Wróbel, 2010), cells in a multicellular body developing from a single cell (Joachimczak and Wróbel, 2008), and cells in a body that both develops and moves in an artificial environment (Joachimczak et al., 2012). Briefly, a genome is a list of genetic elements of 4 types: 2 types of *promoters* (*internal* and *output*), and 2 types of elements coding for *products* (*internal* and *input*). Each element is defined by 4 numbers, specifying its type, a sign, and two coordinates in two-dimensional affinity space.

A series (at least one) of internal promoters followed by a series (ditto) of product-coding elements is a *regulatory unit*. An output promoter is treated as a regulatory unit with a virtual single product (not encoded in the genome explicitly and which cannot bind to promoters), whose activation level translates here to the activity of one of the animat's actuators. There are 2 possible input products: one of them (i_1) is the value received by the food sensor (s) preprocessed by the logarithmic function:

$$i_1 = \frac{1}{7.5} \cdot \log_{10}(s) + 1$$
, (3)

and the second is always set to 1.

All products have continuous concentrations (between 0 and 1). An aGRN can be seen as a graph where vertices correspond to regulatory units, and edges correspond to product-promoter regulatory relationships. The product that regulates a regulatory unit does not need to belong to a different unit—self-regulatory relationships are permitted. When a product and a promoter have the same signs, the relationship contributes to the increase of the concentrations of all the products coded by the regulatory unit to which the promoter belongs. When the signs are different, the relationship contributes to the decrease of these concentrations. The strength of the relationship (the weight associated with the edge) depends on the Euclidean distance between the position of points (specified by the elements' coordinates) in an abstract 2-dimensional space. (This abstract space has nothing to do with the space in which the animats move, it is used solely to model chemical interactions between products and promoters.) When two points overlap, the relationship is the strongest possible. When they are further away than a prespecified distance threshold (5 units), there is no regulatory relationship. The concentrations of products coded by a regulatory unit (L_{Ω}) depend on their previous concentration and the concentrations of all the products with product-promoter relationships with the promoters belonging to the unit:

$$L_{\Omega} = \frac{2}{1 + e^{-(\sum_{j=1}^{J} \sum_{k=1}^{K} L_{k}(m_{k} \cdot m_{i} \cdot \frac{10 - 2d_{k,i}}{10d_{k,i} + 1}))}} - 1, \quad (4)$$

where J is the total number of promoters, K is a the total number of products and inputs in the genome, L_k is the concentration of the product k, $d_{k,i}$ is the Euclidean distance in the abstract space modeling product-promoter interactions, and m_k and m_i are element signs.

The animat gathers food $(0.75 \cdot S \cdot 1vu)$ food in each time unit, where S is food concentration at animat's location, and 1vu is 1 volume unit), and stores it internally. This food (energy) is spent on animat metabolism and movement:

$$\Delta M_t = M_b + M_m \cdot \frac{fa_1 + fa_2}{2} \,, \tag{5}$$

where M_t is the food spent in a time step, M_b is the base metabolism cost (0.003), M_m is the movement cost (0.004), fa_1 and fa_2 are flagella activation levels (values between 0 and 1).

If all food stored internally is spent, the animat dies and decays immediately, providing 4 units food to the environment. When stored food reaches 7 units, the cell divides, and two new animats are created. Division uses 4 units of food, and the rest of food stored by the parent is divided equally between the progeny. As in our previous paper (Erdei et al., 2013), an exact copy of the parent's genome is passed to one cell, and a mutated copy to another. The inheritance without mutation by one cell is inspired by the way elitism is achieved in microbial genetic algorithms (Harvey, 2011). This cell inherits the internal product concentrations from the parent. The cell that receives a mutated genome copy starts with internal product concentrations set to zero—this is necessary because the number of the products may change after the genetic operators are applied.

The mutational process consists of two parts. First, each individual element can change its type, with probability 0.01, or its sign, also with probability 0.01. With the same probability (0.01), both coordinates of an element are modified by a random value from a normal distribution ($\mu=0$, $\sigma^2=5$). Second, the element can originate (with probability 0.002) a duplication or deletion of a chunk of the genome. The number of elements copied (to a random location chosen from the uniform distribution) or deleted is sampled from the logarithmic distribution (with mean 10).

Evolution of tracking strategies

We conducted two sets of experiments, which differed in the speed of food degradation (degradation coefficients 0.98 and 0.97). The size of the environment was 256 length units across. Each experiment consisted of 7 phases. In each phase a group of predators was placed in the environment with specific number of prey (Table 1).

At the beginning of the first phase the environment was populated by 1000 predators with randomly generated genomes and 24 or 30 prey animats (Table 1). After 1 million (in the first phase) or 3 million (in all the subsequent phases) time steps, the number of prey was decreased. The prey count was high initially to enhance the survival of initially inefficient predators, and decreased afterwards so that the higher selection pressure prevents stagnation. We have conducted 20 independent evolutionary runs for each of two values of food degradation coefficient, saving the predator populations at the end of each phase (Fig. 3 and Fig. 4).

After the run ended, the saved populations were tested. In each test, only a relatively small number of predators was used because otherwise bouncing between efficient animats staying close to the prey might influence the results. To make the results as representative as possible for the actual populations, we first chose randomly 500 animats from each

Table 1: The number of prey in consecutive phases of the experiments for different food degradation coefficients.

Phase index	Number of prey for	
r mase mucx	coeff 0.98	coeff 0.97
1	24	30
2	16	24
3	9	20
4	7	16
5	5	12
6	3	8
7	1	4

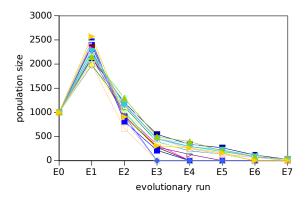

Figure 3: A size of the population for each evolutionary run after each phase (1—7; 0th phase is just 1000 animats which started the first phase) for degradation coefficient 0.98.

(with repetitions only if a population size was smaller than 500), and then separated this sample into 5 equal subsamples. These 100 predators were placed in the environment with 1 prey. During testing, the cells did not die or reproduce (and thus did not evolve). After 100 000 time steps, the mean distance at each time step between the predators and the prey was calculated, and the results for 5 subsamples were averaged. We also measured animats' progress in terms of the speed of gathering energy (the amount of eaten food decreased by metabolism costs) during the evolutionary runs. The initial population was used for comparison, but only one 100 000-step test with 100 predators and 1 prey was used for each run. In some runs no animats survived to the end of the last phase. For instance, only in 8 (for the coefficient 0.98) and 6 (for 0.97) runs there were surviving animats at the end of the penultimate phase (E6).

The results (Fig. 5, Fig. 6, Fig. 7, and Fig. 8) demonstrate that the largest evolutionary progress was made in the first 3 phases. After that the prey following behavior evolved slower or even stagnated. It is possible that the animats cannot follow the prey any closer, because there is a trade-off between moving closer and being pushed away by bouncing. Moreover, sensing changes in the direction the prey moves cannot be immediate (it requires diffusion), and we

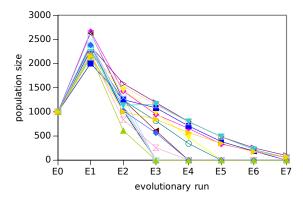

Figure 4: A size of the population for each evolutionary run after each phase (1—7; 0th phase is just 1000 animats which started the first phase) for degradation coefficient 0.97.

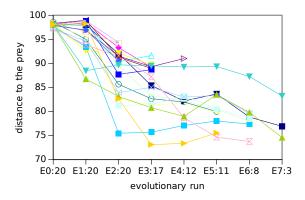

Figure 5: An average distance to the prey over 100 predators in the test environment with degradation coefficient set to 0.98. En for non-zero n is a population after n^{th} phase. E0 is a random population which starts the first phase. The number of populations tested (populations with survivors after each phase) is listed after a colon.

made the task even more difficult by giving the animats only one sensor. Even with those limited sensory abilities, the prey chasing behavior did evolve in the predators (Fig. 9).

Discussion and future work

We present an artificial life system where artificial organisms (animats) evolve without a genetic algorithm. The fitness is implicit and depends on the ability of an animat to find limited resources (food), necessary for reproduction with mutation. We demonstrate that in this system it is possible to evolve animats ("predators") that can follow a food source ("prey") that moves in a random trajectory, even though the predators had only one sensor of food diffusing from the prey.

The setting we used—one sensor, two actuators—is relevant for biological chemotaxis by small (not necessarily unicellular) organisms that cannot sense chemical gradients

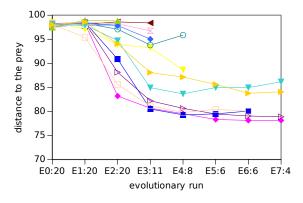

Figure 6: An average distance to the prey over 100 predators in the test environment with degradation coefficient set to 0.97. En for non-zero n is a population after n^{th} phase. E0 is a random population which starts the first phase. The number of populations tested (populations with survivors after each phase) is listed after a colon.

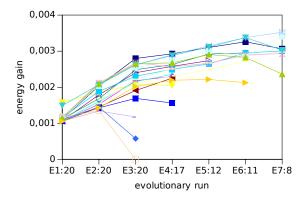

Figure 7: The average value of energy (the amount of eaten food decreased by metabolism costs) gained by one predator in one time step for each phase (E1—E7) of each evolutionary run (degradation coefficient set to 0.98). The number of populations is listed after a colon.

across their body, because their body is small relative to the differences in the concentration in their environment. Such organisms have to rely on temporal integration of information as they move. But the setting we used is not only biologically relevant—it is also applicable for cheap and small (possibly even nanoscale) mobile robots.

An even more challenging setting would be to use one sensor and one actuator; many biological organisms use actuators that can either propel the (possibly unicellular) body forward, or cause a random rotation of the body in space. This is a setting we plan to consider in the future. Even in the setting used here it will be interesting to analyze the fraction of the time in which the animat move predominately forward as opposed to local turning, in relation to the pattern in which the direction of the prey movement changes.

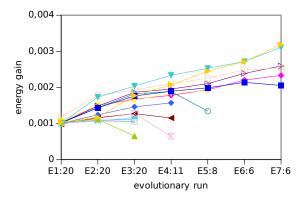

Figure 8: The average value of energy (the amount of eaten food decreased by metabolism costs) gained by one predator in one time step for each phase (E1—E7) of each evolutionary run (degradation coefficient set to 0.97). The number of populations is listed after a colon.

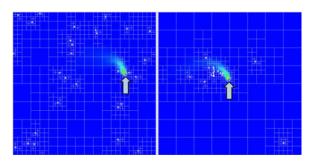

Figure 9: Prey tracking behaviour in evolved predators. The predators (white cicles) disperse all over the environment in the initial population (left), but in the runs with survivors in the last evolution phase (right), the predators remain close to the prey (violet circles indicated by arrows in both panels).

We hope that our system will allow us to test hypotheses relevant for biology and cognitive science, and evolve controllers useful in robotics. Therefore, other possible directions of future work include modifying position and number of sensors and actuators, changing how the sensors and actuators work, and introducing more challenging challenges or environments (e.g., seasonality or diversity of food sources, obstacles). This is the path towards evolution of complex cognitive abilities (Wróbel, 2012)—beyond minimal cognition displayed by predators evolved here.

Abstract

Recent studies have reported that population dynamics and evolutionary dynamics, occurring at the different time scales, can be affected by each other. Our purpose is to explore the interaction between population and evolutionary dynamics using an Artificial Life approach based on a 3D physically simulated environment in the context of the predator-prey and morphology-behavior coevolution. The morphologies and behaviors of virtual prey creatures are evolved using a genetic algorithm based on the predation interactions between predators and prey. Both population sizes are also changed depending on the fitness. We see in the evolutionary simulations two types of cyclic behaviors corresponding to the short-term and long-term dynamics. The former can be interpreted as a simple population dynamics of Lotka-Volterra type models. It is shown that the latter cycle is based on the interaction between the changes in the prey strategy against predators and the long-term change in both population sizes, resulting partly from a tradeoff between their defensive success and the cost of defense.

Introduction

Evolutionary and ecological dynamics have usually been thought to influence each other asymmetrically. Evolutionary changes are usually a consequence of the environment while they occur over timescales that are too long to affect the dynamics of population size in the short term (Schoener, 2011). Therefore, most ecological models ignore evolutionary changes in the conspecific or other species, assuming a separation of timescales between population dynamics and evolutionary dynamics (Hastings, 1997).

However, this assumption is challenged by recent studies on "rapid evolution" in nature occurring on time scales comparable to those typical of population dynamics. In view of such studies, the concept of evolutionary time defined by researchers is changing rapidly (Schoener, 2011). Among them, Hairston et al. go the farthest in defining rapid evolution as a genetic change rapid enough to have a measurable impact on simultaneous ecological change (Hairston et al., 2005). With progress of related studies, many researchers have come to conclude that when rapid evolution occurs during the course of an ecological process, it can significantly change ecological predictions (Fussmann et al., 2007).

Accepting not only that ecology affects evolution but also that evolution affects ecology means that the transformed ecology might affect evolution, and so on, back and forth in a feedback loop, referred to as "eco-evolutionary feedbacks" (Post and Palkovacs, 2009) or "ecogenetic feedback" (Kokko and Lopez-Sepulcre, 2007). The feedback is not entirely straightforward and there are several challenging questions. Among them, the most fundamental one is about the importance of the feedback. It is claimed that only an extensive research effort involving multiple experimental approaches with long-term field experiments over a variety of ecological communities will provide the answer, while the investigations to reveal the role of such feedback are just beginning (Schoener, 2011).

We believe that the Artificial Life approach based on 3D physically simulated environments will provide valuable insights into the relationship and the interaction between population and evolutionary dynamics. The virtual creature models, following the pioneering study (Sims, 1994b), allow us to analyze the morphology-behavior coevolution in 3D environments in the individual level (Taylor and Massey, 2000; Miconi and Channon, 2006; Chaumont et al., 2007; Pilat and Jacob, 2008; Azarbadegan et al., 2011).

Population dynamics can be straightforwardly introduced into these types of models. Population dynamics depends on the fitness of individuals if the fitness represents the offspring number of them in the models, although almost all previous models of virtual creatures have a fixed number of individuals. Given enough computational power, we can observe and analyze the interaction between population dynamics and evolutionary dynamics in 3D virtual creature environments. What we want to emphasize here is that virtually embodied creatures can evolve unexpected traits of morphology and behavior as a result of the interactions with conspecifics or other species in a physically simulated world. Since the genes and parameters do not have explicit pre-defined functions, like they do in previous studies based on mathematical models (Yoshida et al., 2007), functional traits emerge naturally. This makes for more natural evolution and allows us to discuss their emergence in context of

Eco-Evolutionary Dynamics.

Evolutionary process can affect ecological dynamics at intra- and interspecies levels. This study focuses on the predator-prey interactions as the key element of ecological systems (Legreneur et al., 2012). Predation pressures in food chains shape diversity and functions of organisms (Agrawal, 2001). Predators employ various strategies capturing their prey, and at the same time, prey employ various protective mechanisms against their predators in nature (Edmunds, 1974), that can be regarded as the results of the coevolution between predators and prey. Some previous studies using the Artificial Life approach explored competitive coevolution (Sims, 1994a; Miconi, 2008). Our previous model focused on the morphology-behavior coevolution under the environments with a predator and a prey (Ito et al., 2012, 2013a). We extend it to explore the interaction between population and evolutionary dynamics in the context of the predator-prey and morphology-behavior coevolution.

In this paper, we evolve the virtual creatures of the predators and prey with the change in their population size in a 3D physically simulated environment. We analyze the relationship between the population size and the trait evolution and show their two different behaviors depending on the time scale. We then discuss and estimate these interaction and relationship in terms of the population and evolutionary dynamics.

Model

We use Morphid Academy, which is an open-source simulation system (Pilat and Jacob, 2008) to evolve virtual creatures in a 3D physically simulated environment. This virtual creature model is a simplification of Sims' Blockies model (Sims, 1994b) and is fully described in (Pilat and Jacob, 2008). The simplification in body and neural structure reduces the evolutionary search space and has been demonstrated to perform well for various evolutionary tasks. Morphid Academy has been previously used to successfully evolve virtual creatures for locomotion (Pilat and Jacob, 2008), light-following (Pilat and Jacob, 2010), and sustained resource foraging (Pilat et al., 2012). In addition, it has been used to evolve the various successful strategies in one-to-one interaction between a predator and a prey (Ito et al., 2012, 2013a). We performed double coevolution of morphologybehavior and predator-prey couplings, presented the emergence of various morphological and behavioral strategies of prey against predation by predators, and analyzed the dynamics of this coevolution caused by the two levels asymmetries (Ito et al., 2013b).

In this paper, to represent the interaction between the group of predators and prey, we simulate and evaluate every predator and prey individuals of the both population pools in a shared environment (Fig. 1). Each species evolves their traits and change their population size depending on their fitness.

Figure 1: The virtual creatures in the 3D physically simulated environment. The big creatures correspond to the evolved predators and the small creatures correspond to the evolved prey. The semitransparent creature represents a prey caught.

Agent

The agents are virtual creatures comprised of several 3D rectangular solid body parts connected with simple hinge joints. Their physical phenotype is developed from a directed graph (Fig. 2). The nodes represent body parts and the links represent joints. The genotype graph undergoes evolution through a genetic algorithm. We termed the root body part as the torso, and all the other parts as limbs. The controller of a virtual creature is a recurrent neural network embedded in body parts. There are three types of neurons: input, calculation and output. The input neurons represent sensory information from the environment, the computational neurons process the input and the results are fed into other computational or output neurons, and the output neurons as joint effectors power the joints, making the creature move.

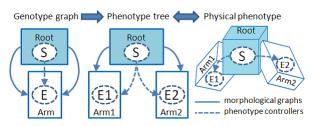

Figure 2: The development from genotype to phenotype.

The sensor of a creature detects a living creature belonging to the other species nearest to the virtual creature within a sensing range s (described in detail in (Pilat and Jacob, 2008) and (Pilat and Jacob, 2010)). Two measures are calculated by the sensor: the angle to the sensed creature with respect to the main orientation axis of the creature and the

distance to the sensed creature. These are combined into one value incorporating the sign of the angle and the value of the distance. The result is fed into the sensory neurons in the network. It is important for this experiment to use a small sensing range s. If the creatures can detect others in distant location with a large s, there is little effect of the density of prey on the predators because the predators are always possible to find any prey in the environment. It causes the decrease in the effect of the population dynamics on the evolution of traits.

Evaluation

In each generation, the predator group and the prey group are randomly positioned within a radius of C from the origin of the simulation space. Every agent is positioned above the simulation plane and allowed to free-fall due to gravity during a stabilization phase. Once they become stable resting on the ground surface, the an encounter phase for the evaluation begins and lasts for S simulation time steps.

Capturing is defined as the predator touching the torso of the prey with any of the predator's body parts. This definition represents that animals have a weak point in their body. The captured creature is disabled and cannot be sensed until the end of the simulation.

The evaluation value of each agent after the predator-prey encounter (the encounter phase) is calculated using Eq. 1 and 2. The evaluation value of a predator is defined by Eq. 1:

$$EV_{predator} = \begin{cases} \alpha_1 \times \{S_p + (1 - \frac{d_n}{d_0})\} & (\frac{d_n}{d_0} < 1) \\ \alpha_1 \times S_p & (\frac{d_n}{d_0} \ge 1), \end{cases}$$
(1)

where α_1 represents the parameter that adjusts the size of evaluation. S_p represents the number of successful predation by the focal predator. d_n represents the distance from the prey detected by the focal predator in the final simulation step and d_0 represents the distance between them when the focal predator began to detect that prey. This equation means that the predator that captures more prey and that tends to approach prey can obtain the larger evaluation value.

The evaluation value of a prey is defined by Eq. 2:

$$EV_{prey} = \begin{cases} \alpha_2 \times (1 - \frac{v}{\beta}) & (\text{escaped}, v < \beta) \\ 0 & (\text{caught}) \\ 0 & (\beta \le v), \end{cases}$$
 (2)

where v represents the volume, the parameter α_2 represents the parameter that adjusts the size of evaluation and β represents the coefficient for the maintenance cost of the larger volume. This definition of the evaluation value function means that the prey that has successfully escaped predation until the end of the simulation obtains a evaluation value but its size depends on its volume, which represents the cost for the maintenance of the large body. When the prey is captured or when the volume of the prey is larger than β , the evaluation value is 0.

Evolution and Population Dynamics

Two populations representing the predators and the prey are concurrently evolved for g generations using a genetic algorithm. Both population sizes P1 and P2 are changed simultaneously with the reproduction of the next generation. We used the following process for the genetic algorithm.

Each individual has an opportunity to reproduce some children by mating with another individual selected randomly. The expected value of the number of offspring n ($0 \le n \le M$) for the mating event is defined by the fitness based on the evaluation values of the both parents using Eq. 3:

$$Fitness = \frac{\text{Sum of the parents' evaluation value}}{D}, \qquad (3)$$

where the parameter D represents the difficulties of the reproduction. Note that if the number of the children exceeds the lower (upper) limit of the population $P1_{min}$ and $P2_{min}$ ($P1_{max}$ and $P2_{max}$), one (no) child is created by the parents, and thus the population is kept at the lower (upper) limit.

The parents produce n children through one of the genetic operators: copying (with the probability R_p), crossover (with R_c), and grafting (with R_g). A single point crossover exchanges parts of the genotype tree at the node level. The grafting operator grafts a randomly chosen subgraph from one parent onto another. A mutation is applied to the resulting child individual with the probability R_m , which applies small changes to the whole genome (with the probability 0.05 per gene). This change includes changes in the morphological node or link parameters, addition of morphological nodes, and the addition or removal of morphological links. The resulting creature is processed to remove unreachable nodes. The children of every individuals replaces the population. As a result, the population size is changed according the fitness of creatures.

Results

Experimental Setting

In the experiments as a first step in the new direction, we assumed that the prey population evolved as described above while the predator population did not evolve in order to understand the basic dynamics caused by evolution of one species. For this purpose, we pre-evolved the predators in preliminary experiments with random prey, and some successfully evolved predators were used to seed the initial population of predators. On the other hand, the random prey were used to seed the initial population. We also used the evolutionary parameters as follows: $R_p=1.0$, $R_c=0.0$, $R_g=0.0$ and $R_m=0.0$ for the predator population without evolution; and $R_p=0.8$, $R_c=0.1$, $R_g=0.1$ and $R_m=0.1$ for the prey population with evolution. We further used the following settings of parameters: g=1000, S=100000, S=300, C=1500, $P1_{max}=50$,

 $P2_{max} = 50$, $P1_{min} = 5$, $P2_{min} = 5$, $P1_0 = 25$, $P2_0 = 25$, $\alpha_1 = 10000$, $\alpha_2 = 10000$, $\beta = 50$, D = 6000 for predator, D = 6000 for prey, and M = 3.

Basic Behavior

We performed 10 trials of evolutionary experiments using those settings. We observed a similar tendency of the population dynamics in all the trials. Fig. 3 and Fig. 4 show the typical population dynamics and the change in the average fitness of predators and prey, respectively.

In these figures, the red line and the blue line represent the population size (fitness) of the predators and prey, respectively. In early generations, both populations were very low. At some point near the 250th generation, both populations increased suddenly and then started to fluctuate significantly. The change in the prey population was larger than that in the predator population in this period. After that, around the 600th generation, the both populations became very low, which is the similar to those in the early generations. Finally, around the 750th generation, both populations increased again. As this shows, it has the different two patterns of the population dynamics occurred alternately. In addition, we see that the fitness of both populations also changed in synchronization with their population size.

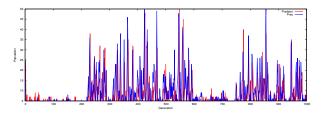

Figure 3: The typical result of the change in the population of the predators (red line) and prey (blue line).

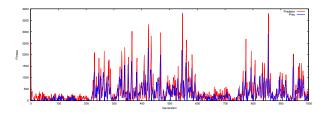

Figure 4: The typical result of the fitness of the predators (red line) and prey (blue line).

Population and Evolutionary Dynamics

We analyzed the relationship between the population and evolutionary dynamics of both populations. As the quantitative index of the evolutionary dynamics, we used the average volume of the body and tracked its evolution.

Short-Term Dynamics First, we focused on the period from the 300th to 400th generations that showed the typical population change in a short-term dynamics. Fig. 5 shows the populations of the predators (red line), prey (blue line) and the average volume of the prey (green line). We observed a periodic increase and decrease of the both populations and also observed that the change in the prey population preceded the change in the predator population. We estimated by time delay estimation (TDE) method (Chen et al., 2003) that the change in the prey population was followed with a time lag of about 2 generations by the change in the predator population.

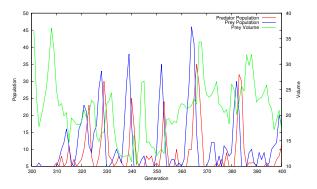

Figure 5: Population of the predators (red line) and prey (blue line) and the average volume of the prey (green line) from the 300th to 400th generations.

Long-Term Dynamics Second, we focused on the relationship in a long-term dynamics using a 30-period simple moving average of the indices in order to reduce the short-term fluctuations. Unlike those in a short-term period, the populations of the predators and prey changed simultaneously as shown Fig. 6. Both species had large populations at the 0th to 200th and the 600th to 750th generations and had small populations at the 200th to 600th and the 750th to 1000th generations. On the other hand, when the population of the prey gradually increased (decreased), the volume of the prey slightly decreased (increased) simultaneously.

Trajectory Analysis We can see the difference between these dynamics more clearly by focusing on the typical trajectories of population and evolutionary changes in a short-term dynamics (A and B) and a long-term dynamics (C and D), shown in Fig. 7. The trajectory of the predator and prey populations shows a typical cyclic behavior in the short-term dynamics (A), which is often observed in Lotka-Volterra systems (Vorterra, 1926; Lotka, 1932). In this case, the trajectory of the volume and the population of the prey showed no clear tendency (B), and the correlation coefficient was -0.30. This means that there are no interactions between the population and evolutionary changes of the prey.

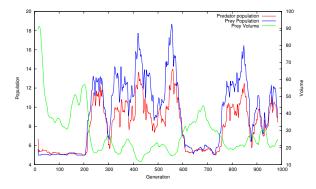

Figure 6: Population of the predators (red line) and prey (blue line) and the average volume of the prey (green line) smoothed by a 30-period simple moving average.

On the other hand, the graph C shows that there is a positive correlation between the predator and prey populations in the long-term dynamics. This is different from the one in A although we can still see small cycles in the trajectory. It also should be noted that, in the graph D, there is a strong negative correlation between the population and volume of the prey, and the correlation coefficient was -0.75. This means that there existed clear interactions between the population and evolutionary changes in this long-term dynamics. We also see the oscillations of these indices occurred repeatedly, keeping the correlation negative.

Thus, we can say that the mutual interactions between the population and evolutionary changes were observed only in the long-term dynamics.

This result suggests that the population and evolution dynamics had the different relationship between the short-term and the long-term dynamics. Especially, it is expected that the evolutionary dynamics strongly affected the population dynamics in a long-term dynamics, in contrast, it affected little in a short-term dynamics.

Influence of Population Dynamics on Evolutionary Dynamics

Next, we analyzed how the population dynamics affected the evolutionary dynamics of the prey. There are two factors as selection pressures on the prey: defense against predation and reduction in cost of defense, as is defined in Eq. 2. In our previous study (Ito et al., 2013a), we observed that the large volume was necessary for the prey to obtain the successful defensive strategies. Therefore, there is a trade-off between these two factors because the large volume is costly in our experiments. Theoretically, on some conditions, the change in the average value of a trait depends on the covariance between the trait and its fitness or, equivalently, the regression coefficient of fitness on the trait multiplied by the variance of the trait (Steven, 1998). In this model, we focus only on the

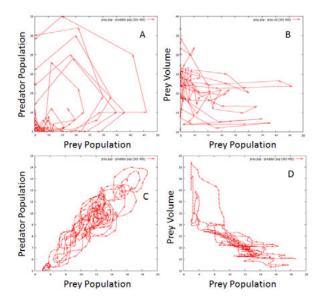

Figure 7: Typical trajectories of population and evolutionary dynamics. We used the data in Fig. 5 and Fig. 6 for plotting the graphs "A and B" and "C and D", respectively. (A) The predators and prey populations in short-term dynamics. (B) The volume and population of the prey in short-term dynamics. (C) The predators and prey populations in long-term dynamics. (D) The volume and population of the prey in long-term dynamics.

variance of the trait for simplification. We estimated from which selection pressure the prey population was affected by observing the relative variance RV_c , which is defined by following equation:

$$RV_c = \frac{V_c}{V_c + V_p} \tag{4}$$

where V_c is the variance of cost (= volume) and V_p is the variance of the successful escape from the predation.

Fig. 8 shows the predator population (red line) and the relative variance of the cost (black line). The relative variance of the cost increased while the size of the predator population decreased and the relative variance of the cost decreased while the size of the predator population increased. Therefore, the pressure of the predation tends to dominate in a large predator population and the pressure of the cost tends to dominate in a small predator population. It is adaptive for the prey to reduce the cost in an environment in which the predator population is small. The prey without defensive strategies with the lower cost can obtain the high fitness, because the probability of predation is low. In contrast, it is adaptive for the prey to increase the cost and have defensive strategies in an environment in which the predator population is large. If the prey escape from the predation by paying

the high cost, it is expected that they obtain the higher fitness than that in the case of paying a low cost because of the high risk of predation.

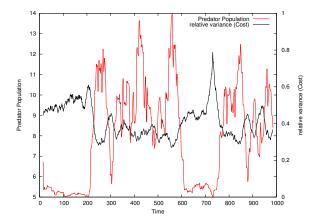

Figure 8: The predator population (red line) and the relative variance of the cost (black line).

Discussion

We discuss the two different types of the interactions between the population and evolutionary dynamics with different time scales observed in the previous experiments, which were illustrated in Fig. 9 and 10. In each figure, the outer and inner circular arrows represent the dynamics in the population level (i.e., change in the size of both populations) and the individual level (i.e., the evolution of the volume of the prey), respectively. The middle circular arrows represent the change in the target of selection.

Short-Term Dynamics

Fig. 9 shows their interactions in a short-term dynamics, which can be summarized as follows:

- 1. When the predator population is small, the prey population is increased by the low probability of predation.
- 2. The increase in the density of the prey population causes the increase in the probability of successful predation and the increase the in predator population.
- 3. The prey population is decreased by the large predator population due to the successful predation of the prey by the predators.
- 4. Finally, the predator population decreased caused the low density of the prey population. The both populations return to the step 1.

This cyclic dynamics corresponds to the one observed in the Lotka-Volterra systems, which is caused by the change in the

population density only. In this short-term dynamics, there seems no clear selection pressure for the trait of the prey. It is assumed to be due to the fact that population dynamics of both species were too fast for the prey population to adapt to, although it is too simplistic to conclude that evolutinary dynamics does not affect short-term population dynamics in this model.

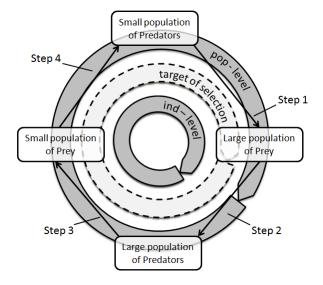

Figure 9: The interactions between the population and evolutionary changes in the short-term dynamics.

Long-Term Dynamics

Fig. 10 shows their interactions in a long-term dynamics, which can be summarized as follows:

- 1. When the predator and prey population are small, the probability of predation is low. Therefore, the reduction in the cost of defense becomes the target of selection.
- 2. The volume of the prey decreases.
- 3. Because the prey with the low cost body obtain high fitness and reproduce many offspring, the population of the prey increases. At the same time, the increase in the density of the prey population causes the increase in the predator population.
- 4. When the predator and prey population are large, the probability of the predation is high. Therefore, defense against predation becomes the target of selection.
- 5. The effective defensive strategies with the large volume of their body invade into the population of the prey.
- 6. Because of the high cost for their large volume as well as the high predation pressure, they get low fitness. Thus, the

population of the prey decreases, which further decreases the population of predator. Both predator and prey population return to the step 1.

In this long-term dynamics, there is enough time for the evolution process of the prey to adapt to their environmental condition because the change in the population of predators is relatively slow. Thus, the trait evolution of the prey occurred in response to the population dynamics of the predators, which further brought about the change in the population dynamics. This implies that there exists an appropriate timescale for the complex interactions between the population and evolutionary dynamics to emerge.

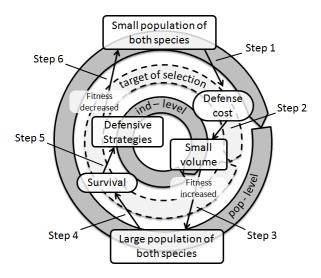

Figure 10: The interactions between the population and evolutionary changes in the long-term dynamics.

Recently, there have been various reports on the interactions between the population and evolutionary dynamics. As for the interactions in the predator-prey relationship, Yoshida et al. showed that there is a trade-off between the competitive ability and the defense against predation of the prey in rotifer-alga and phage-bacteria chemostats. The most competitive non-predator-resistant bacteria dominated initially, but as rotifer densities increased, the more predatorresistant bacteria dominated (Yoshida et al., 2004). They also showed that the predator or pathogen can exhibit largeamplitude cycles while the abundance of the prey or host remains essentially constant (Yoshida et al., 2007). They found that, in such a situation, there exist the cryptic cycles of interactions between these species through the rapid evolution of the frequencies of defended and undefended prey. Sanchez and Gore also demonstrated the presence of a strong feedback loop between population dynamics and the evolutionary dynamics of a social microbial gene, SUC2, in laboratory yeast populations whose cooperative growth

is mediated by the SUC2 gene (Sanchez and Gore, 2013). They showed that the eco-evolutionary trajectories of the population density and the gene frequency spiral in the density/frequency phase space. The long-term dynamics observed in our experiments is expected to be the first demonstration of such eco-evolutionary feedbacks in a 3D artificial creature model. We believe that our approach allows us to analyze the emergent process of various morphological and behavioral strategies in this context.

Conclusion

We presented the results of evolutionary experiments investigating the interaction between the population dynamics and the trait evolution of a predator-prey scenario in a 3D physically simulated environment. The morphologies and behaviors of virtual prey creatures are evolved using a genetic algorithm based on the predation interactions between predators and prey. We also changed the population size of both species depending on the fitness of individuals.

We found the different interactions between population and evolutionary dynamics at short and long timescales. When we focused on the short-term dynamics, we observed a simple cyclical dynamics of the population of predators and prey, which corresponds to a Lotka-Volterra type population dynamics. This is because the population dynamics was too fast for the evolutionary dynamics to adapt to. In contrast, when we focused on the long-term dynamics, we observed the complex interactions between the population dynamics of both species and the evolutionary dynamics of the trait of prey. Specifically, we found the inverse correlation between the population sizes and the average volume of the prey, and their continual fluctuations, yielding the emergence of defensive and non-defensive morphological strategies of prey. This is due to the fact that the target of selection for the prey switched between defense against predation and reduction in cost of defense depending on the population size of predators.

That is, the change in the population size caused the change in the selection pressure and the change in the trait caused the population change. We believe that such dynamics can be observed in predator-prey scenarios both in artificial frameworks and in nature.

Our model could be extended in various directions. One obvious direction would be to evolve the predators simultaneously. Such extended evolutionary experiments may show the population and evolutionary dynamics in the predator-prey relationship more clearly. Furthermore, we believe that the dynamics selection pressure exerted by an evolving predator would likely be a major factor in shaping the population and evolutionary dynamics, leading to more complex dynamics than the monotonous repetition of a similar evolution of the volume observed in this paper. Another direction would be to add intra-species interaction to support group hunting and prey herding behaviors and shed light on their

effect on the population dynamics.

Building on Simplicity: Multi-stage Evolution of Digital Organisms

Laura M. Grabowski, Javier A. Magaña

Department of Computer Science, The University of Texas–Pan American 1201 W. University Drive, Edinburg, Texas, 78539 grabowskilm@utpa.edu

Abstract

The issue of how complex organismal features and functions arise through evolution remains a topic of great interest to researchers. We used digital organisms to investigate how simpler capabilities that evolved earlier may provide stepping stones for evolving new features. Populations of digital organisms evolved in environments of varying complexity where survival required different uses of memory. We conducted experiments that used different initial ancestors for populations: (1) an ancestor with only the ability to selfreplicate, evolved in each of the four types of experimental environments; (2) successful organisms from one environment seeded populations that continued to evolve in one additional environment ("one level" transfer); (3) successful organisms were transferred progressively from the simplest environment to the most complex ("waterfall" transfer). We found that the difference in performance of the most successful organisms at the end of evolution was significantly different (1) when the original environment differed little from the new environment, and (2) when the original environment produced adaptations that provided memory and use of previous life experience.

Introduction

In order to survive, organisms have evolved many complex adaptations. Even simple organisms have complex functions and structures. Bacteria communicate using secreted molecules to coordinate the behavior of the group. In other organisms, complex hierarchical regulatory circuits have evolved to integrate and process sensory information (Brelles-Marino and Bedmar, 2001). Many complex adaptations gave rise to brains that are capable of extracting patterns from a noisy, non-stationary, and often unpredictable environment. Brains control and coordinate movement, form memories, and construct models of the world and its dynamics (Koch and Laurent, 1999).

The manner in which complex features such as brains evolve is a key issue in evolutionary biology. Insight into this issue helps explain the presence of biological complexity and provides inspiration to computer scientists and engineers. Investigating the evolution of complexity can provide guidance in how we create and use new technologies, including drug therapies, the Internet, and self-replicating robots.

Trying to find effective ways to improve on these technologies is challenging, but identifying how basic elements affect complexity may lead to new and more effective solutions to complex problems.

Coyne (2009) describes natural selection as a "tinkerer," doing the best it can with what is available at the time. In the natural world, evolution through natural selection has repeatedly produced highly complex traits. To understand the details of how evolution produces something as complex as a brain, we would need a perfect fossil record, ideally including the genetic information for the entire line of descent. This ideal situation rarely exists in the natural world, making such analysis hard to perform in living organisms. Digital evolution, an approach within the larger discipline of artificial life, offers a potential solution to many of the problems involved with studying evolution in living organisms. Digital evolution systems allow us to track evolution as it occurs, producing the complete record we need for analysis. Researchers can observe and analyze the evolving population without disturbing the environment, something that is nearly impossible to do in natural systems. Investigators are also able to control most aspects of the evolutionary environment so that hypotheses can be tested with proper experimental control. This degree of control is difficult to achieve with natural systems.

Many researchers have explored issues of complexity. The notion of complexity can be viewed in a number of ways. These different perspectives are reflected in the variety of approaches to exploring the topic. Adami et al. (2000) measured genomic complexity in digital organisms using information theory. Adami et al. showed that genomic complexity increases under the influence of natural selection, as mutations that allow organisms to survive (i.e., informative mutations) are preserved in the genome. Goldstein (2009) applied fluid dynamics principles to the question of the evolution of multicellularity, hypothesizing that the transition to multicellularity was connected to competing aspects of fluid dynamics. Lenski et al. (2003) provided a strong demonstration of the emergence of functional complexity, the degree of complexity of the realized function.

Their study showed that there are functional relations between simpler and more complex functions, and that simpler functions may be used to evolve more complex functions. In that study, Avida organisms evolved to perform nine logic functions of increasing complexity. Of the 50 experimental populations, 23 populations evolved the most complex task, logical equals (EQU). In another set of experiments for the study, organisms were rewarded for performing EQU, but not for performing any of the simpler tasks. In this setup, none of the populations evolved EQU. The authors' analysis revealed that the complex task required building blocks provided by the simpler tasks that came earlier in evolution.

In this paper, we present results related to the evolution of functional complexity. Digital organisms evolved in different environments where success required different uses of memory. The complexity of the task related to the level of memory use required to execute the task. To test the hypothesis that simpler functions that evolved earlier provided building blocks for more complex functions, we used three treatments with different initial ancestors for the evolving populations.

Avida Overview

The Avida Digital Evolution platform (Ofria and Wilke, 2004) places a population of self-replicating computer programs (called digital organisms or Avidians) in a computational environment. Avida provides the basic ingredients necessary for evolution: replication, competition and variation (Dennett, 2002).

The Avida world, or population grid, is a two-dimensional grid of cells, each of which may contain at most one digital organism. Each individual organism is made of a circular list of assembly language-like instructions, its "genome," and a virtual central processing unit (CPU). The standard Avida virtual CPU consists of three registers, two stacks, and several heads. Each instruction in the genome modifies the virtual CPU, and the cost of executing the instructions is measured in virtual CPU cycles. Avidians perform all internal operations and interact with the world through executing their instructions.

Most Avida experiments are seeded with a simple self-replicating ancestor, *i.e.*, an organism that has only the ability to copy itself into a space of memory that will become its offspring. When the digital organisms copy themselves (*i.e.*, self-replicate), there is a possibility for variations, or mutations. Mutations in Avida can be an addition, deletion, or change of Avida instructions in the offspring's genome. When an organism has finished its replication, the offspring's genome is divided from that of the parent, and the offspring is placed in a grid cell in the population grid, replacing any other organism that occupied that location. Thus, the fundamental competition in Avida is created by the limited space in the environment. An Avidian that can replicate faster has an advantage over slower replicators because

the faster replicating organism will have a higher probability of more descendants in future populations than a slower Avidian. Execution speed is variable, and is determined in part by an organism's metabolic rate. The metabolic rate is used to allocate virtual CPU cycles, and a higher metabolic rate increases the speed the Avidian can execute instructions by allocating it more virtual CPU cycles in the current time slice. Avidians may increase their metabolic rate by performing tasks related to success, such as performing logic operations or following a path.

In our experiments, we use an Avida environment type called the state grid (Grabowski et al., 2010, 2011, 2012, 2013). The state grid, or behavior grid, is a virtual environment separate from the Avida population grid, where each organism has separate information about its environment. While a digital organism stays in the same position in the Avida population grid, each Avidian has a virtual grid where it can move independently of other organisms in the population. The only interaction between individuals in behavior grid experiments is when a newly produced offspring replaces another organism in the population grid. The behavior grid allows simplification of the experimental design and implementation of experiments, is easily defined and understood by human experimenters, and runs with efficiency and relatively low computational overhead.

Methods

Evolutionary environments

Each behavior grid contains a single path for the Avidians to follow. The path is formed by placing a sensory cue in each grid cell. Avidians may sense the cue in the cell if they execute a sensing instruction. The cues do not provide any information to the organisms about what to do with the sensory information; organisms must decide what use to make of the sensory cue, if any. The concept behind the environments is that an organism moves around the behavior grid environment, encountering different states that either increase or decrease the organism's energy by increasing or decreasing the metabolic rate bonus. When an organism moves along the path, it encounters "food" states that supply more energy than the amount of energy lost through movement. If an organism moves to a location off the path, it will not receive energy since those cells do not contain food. The more steps the organism takes off the path, the greater the amount of energy wasted, reducing the overall metabolic rate bonus. Organisms that move along the food path build up energy, and are able to execute at an accelerated rate.

The environmental cues or signals in the behavior grid paths vary depending on the experimental design. We used the following cues to construct behavior grid paths:

• *Empty*: indicates that the organism is off the path. Movement in empty cells reduces metabolic rate bonus.

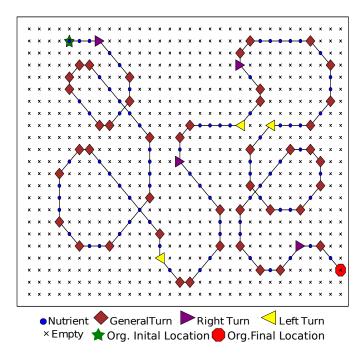

Figure 1: Example environment for the General-turn (GT) experiments. GT environments contain all sensory cues used to construct behavior grid paths.

- *Nutrient*: indicates that a cell is on the path and contributes to the metabolic rate bonus the first time that the organism occupies the cell.
- Directional cue: signals a turn (either right or left) in the path. All turns are 45° increments. Turn cues are treated as nutrients, adding to the metabolic rate bonus.
- General-turn cue: signals the repetition of the most recently encountered directional cue and also contributes to the metabolic bonus.

Different environments are created by using different cues for the paths. The configurations of our paths were inspired by maze-following experiments with honey bees (Zhang et al., 1996). For our experiments, we used the following environment types:

- *Single-turn (ST)*: paths that have directional cues in only one direction, right or left.
- Right-left (RL): environments containing both left and right directional cues in the same environment.
- Cue-first (CF): the first turn signal (i.e., right or left directional cue) in the environment specifies the direction of the rest of the turns, which are indicated by general turn cues. All turns in each environment are in the same direction (right or left).

• General-turn (GT): contains a combination of left and right directional cues, along with the general turn cue. The explicit directional cue appears when the direction of turn changes from the preceding turn (e.g., when the last turn was to the right and the current turn is to the left). Otherwise, the general turn cue appears. Figure 1 shows an example GT environment.

Each environment is slightly more complex than the previous one in terms of the memory needed for success in the environment. In ST environments, Avidians must handle only one directional cue type in each environment. For RL environments, organisms must respond to both types of directional cues. The ST and RL environments require only a simple mapping from the sensory input to the necessary action. The CF and GT environments, however, require that organisms make behavioral decisions based on both the current sensory input and past life experience. In CF environments, that experience is the specific directional cue that was sensed at the first turn on the path. Once the organism successfully maps the general turn to that initial explicit directional cue, it does not need to update that mapping during its lifetime. For GT environments, the organism must remember the most recent directional cue. GT environments require the ability to remember the last directional cue and update that memory at irregular intervals while traversing the path. A successful solution for the GT environment is also a successful solution for all the other environments. Each environment is a sub-problem of the subsequent environment.

Organisms receive a metabolic rate bonus for a path traversal task (Grabowski et al., 2010), accruing increasing bonuses as they move farther on the path. If an organism travels the entire path without stepping off, it receives the maximum possible bonus. Organisms receive the bonus only for the first time they enter a path cell, discouraging them from evolving to oscillate between cells. Any movement off the path is considered a waste of energy, and therefore all movement off the path reduces metabolic bonus.

Task quality (TQ) provides a measure of how well an organism traverses a path, reflecting the proportion of the path an organism travelled without making mistakes. The calculation of task quality is simply

$$TQ = ((valid - empty)/pathLength)$$

where (valid-empty) is the difference of the count of unique (i.e., non-duplicate) path cells encountered (valid) and the total count of empty cells (empty) encountered, and pathLength is the total count of path cells (nutrients and directional cues). Task quality must remain non-negative. If valid-empty becomes negative, task quality is set to 0. Task quality values range from 0 to 1, with 1 the best possible task quality value. Avida tracks the task quality throughout evolution, recording the maximum task quality (MTQ). The MTQ value is the highest task quality among all organisms in the population at the moment the measurement

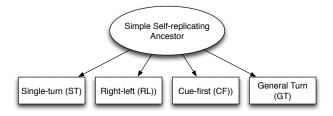

Figure 2: Control experiments. Populations in all experimental environments were seeded with the simple self-replicating ancestor (a digital organism with only the ability to replicate).

is recorded. To provide aggregate task quality information across all populations, we use the average maximum task quality (AMTQ). AMTQ takes the average of the MTQ values for all populations at each recorded time point, allowing us to look at what happened to the MTQ values throughout evolution.

Experimental Setup

We used three treatments for experiments, one which served as a control and two experimental treatments. For the control (Figure 2), we seeded populations in each of the four environment types described above (ST, RL, CF, GT) with an organism with only the ability to replicate. The control populations established a baseline against which to compare the experimental populations, and replicated results of earlier work (Grabowski et al., 2010, 2011, 2012). For each type of environment, we used eight different path configurations. Each organism was assigned a path at random when it was placed in the population grid. All experiments ran for 250,000 updates (the native unit of time in Avida, equivalent to around 10,000 generations in these experiments).

The purpose of the experimental treatments was to probe how earlier adaptations affect further evolution. For these experiments, organisms that evolved in one environment were transferred to, and continued to involve in, a different environment. For both treatments described below, we ranked the populations by maximum task quality at the end of evolution and took the best organism from each of the top five populations. Each of these five organisms served as the initial ancestor for ten new populations in the new environment. Experimental treatments differed according to the number of different environments organisms were exposed to during evolution, as described below.

1. **Experiment 1: "One level" transfer.** The top five organisms from each of the first three environments in the control experiments (ST, RL, CF) were transferred to the next most difficult environment. The one level transfers are illustrated in Figure 3.

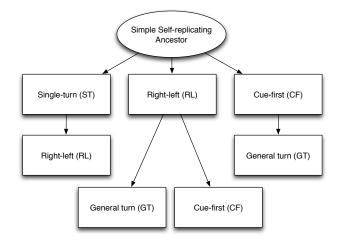

Figure 3: One level transfer experiments. Populations in all experimental environments were seeded with organisms that had evolved in one prior environment.

2. Experiment 2: "Waterfall" transfer. In this treatment, evolved organisms were transferred progressively from the simplest environment (ST) through the most complex environment (GT). Evolved organisms from the ST control experiments served as the ancestors for the RL environment populations, as described above (see Experimental Setup). After evolution in this new environment, the most successful organisms became the ancestors for populations in both the CF and GT environments. After additional evolution in the CF environment, successful organisms seeded more GT environment populations (Figure 4).

In both experimental treatments, we used two different transfer "pathways" into GT environments (RL to GT, and CF to GT). This approach allowed us to test which sub-problem—and its corresponding previously evolved ability—bestowed more of an advantage, the ability to handle both right and left turns in the same path or the ability to remember a past action.

Results and Discussion

One Level Transfer Experiments

As described above, the ancestor organisms for these experiments were the highest fitness organisms from the top five control populations, ranked by task quality. Each of the five organisms was the ancestor for ten new populations in the transfer environment. Not all of the new populations survived the transfer, *i.e.*, some populations died out before the planned end of the experiment. Table 1 summarizes MTQ and survival information for the one level transfer experiments.

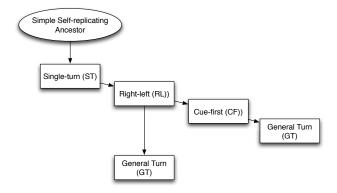

Figure 4: Waterfall transfer experiments. Top organisms from the control experiments in the ST environment seeded new populations that evolved further in RL environments. Organisms from the most successful of those populations then seeded new populations in CF and GT environments. After more evolution in the CF environment, organisms from top performing populations seeded new populations in the GT environment.

Single-turn to Right-left environments (ST-RL) The top five ranking organisms from ST environments were transferred to RL environments. Since these organisms' ancestors were exposed to both right and left turn paths during the course of evolution in the ST environment, we hypothesized that the transfer populations would be able to evolve a solution faster than the control populations that evolved from scratch (de novo). Our data support this hypothesis. In fact, the transfer populations evolved the capability to traverse the entire path correctly in a short time, and maintained that ability throughout the duration of the experiments. The difference in maximum task quality (MTQ) values between the transfer populations and the populations evolved de novo is statistically significant (Mann-Whitney, p < 0.05). Figure 5 shows the distributions of the MTQ values at the end of evolution for both treatments, illustrating that all the ST-RL transfer populations have TQ values very near 1.0. The ST control populations have a high mean, but more variation in the overall distribution of TQ values.

Right-left to Cue-first environments (RL-CF). In the the Right-left to Cue-first (RL-CF) transfer experiments, only two of the five seed organisms survived the transfer to the new environment. Thus, only 20 of 50 populations survived to the end of the experiment. All of the surviving populations come from the third and fifth ranked organisms transferred from the RL environment.

Figure 6 shows that the AMTQ of the transfer populations was higher than that of the control populations at the beginning of the experiments. As evolution progressed, the AMTQ of the control populations passed that of the transfer

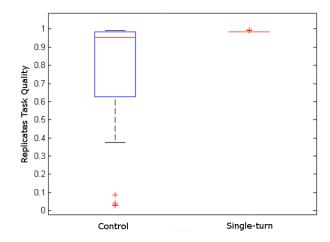

Figure 5: One level transfer experiments, Single-turn to Right-left environments (ST-RL) and Control. Top organisms from the control experiments in the ST environment seeded new populations that evolved further in RL environments. Plot shows the distribution of maximum task quality (MTQ) values for all replicate populations at the end of evolution for the two treatments. The difference in the MTQ values is significant (Mann-Whitney, p < 0.05).

populations. Although some of the individual transfer populations did well, in general they did not fare as well as the control populations that evolved from scratch in the CF environments. Of all of the transfer populations that survived to experiment completion, only two produced organisms that were able to successfully traverse the Cue-first environment paths. Both of these organisms evolved from the fifth-ranked transfer ancestor.

Right-left to General-turn environments (RL-GT). The results of the Right-left to General-turn (RL-GT) transfer experiments echo those of the RL-CF experiments. Only 20 of 50 populations survived the experiment, with ten of the surviving populations descended from the third-ranked seed organism, and the other ten from the fifth-ranked seed organism. Figure 7 shows the AMTQ values for all treatments for GT environments (control populations, RL-CF transfers, and experiments discussed in the next two sections, CF-GT transfers, and waterfall transfers). The AMTQ of the GT and the RL-GT experiments are very close to each other. At the beginning of evolution, the transfer populations perform better than the controls. As evolution continues, the control populations surpass the AMTQ of the transfer populations. The transfer populations appear to evolve some improvements at intervals, so that the AMTQ of the transfer populations approaches that of the control populations. The populations that evolved from scratch steadily increase performance over time, but are surpassed by the transfer pop-

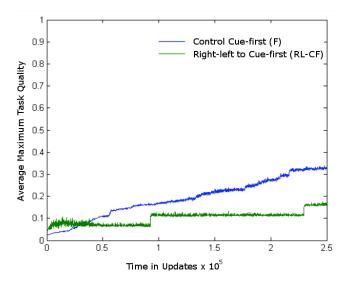

Figure 6: One level transfer experiments, Right-left to Cuefirst environments (RL-CF), and Control. Top organisms from the control experiments in the RL environment seeded new populations that evolved further in CF environments. Transfer populations initially had higher task quality than the control populations, but failed to make much progress over evolution. The control experiments continued to improve slowly throughout the course of evolution, ending the experiment with a significantly higher AMTQ than the transfer populations (Mann-Whitney, p < 0.05).

ulations just before the experiment finishes. However, the difference in AMTQ at the end of experiments is not significant (Mann-Whitney, p>0.05). The individual organism with the greatest task quality was from a RL-GT transfer population, and had an AMTQ of 0.9926, indicating near perfect traversal of the path. Figure 8 shows the distribution of MTQ values for the RL-GT populations and the control GT populations.

Cue-first to General-turn environments (CF-GT). Some of the most interesting results came from the Cue-first to General-turn transfer experiments (CF-GT). 28 of 50 populations survived the experiment, with surviving populations descended from the first, second and fourth ranked seed organisms.

Figure 7 shows that the CF-GT produced the best AMTQ among the GT experiments for all treatments discussed so far. The transfer populations performed better than populations from other treatments from the start, reaching an AMTQ of 0.5 before the midpoint of the experiment, with a steady increase throughout the remainder of evolution. By the end of the experiment the populations had an AMTQ greater than 0.6. Figure 8 shows the MTQ distribution from the GT, the RL-GT, and CF-GT experiments. There is a significant statistical difference between the CF-GT

Experiment	Surviving Replicates	Replicates with MTQ > 0.9
ST-RL	40	40
RL-CF	20	2
RL-GT	20	4
CF-GT	28	7

Table 1: Summary of one level transfer experiments. "Experiment" identifies the evolutionary environment of the ancestor and the environment to which the evolved organisms were transferred. For example, "ST-RL" denotes that the ancestor evolved first in the ST (Single-turn) environment and was then transferred to the RL (Right-left) environment. "Surviving Replicates" is the total number of replicates (populations) that survived until the end of the experiment in the new environment. "Replicates with MTQ > 0.9" gives the number of surviving populations that produced a Maximum Task Quality (MTQ) above 0.9 at the end of evolution.

and the other two groups, GT and RL-GT (Kruskal-Wallis, $p < 0.05). \label{eq:groups}$

Waterfall Transfer Experiments

The waterfall transfer experiments begin with the control experiments evolving in ST environments. The top five organisms from the ST control experiment are then used to seed populations in RL environments. The top five organisms from these transfer populations are used to seed populations in both CF and GT environments. Finally, the top five organisms from the CF transfer populations seed new populations in GT environments. In the one level transfer experiments discussed above, many populations did not survive the transfer to the new environment. Survival was not an issue, however, in the waterfall transfer experiments, since all the populations survived to the end of the experiments.

ST-RL-GT Waterfall Transfer. The ST-RL-GT waterfall experiments produced the lowest AMTQ among all the treatments discussed so far. Figure 7 shows the AMTQ for GT populations from all treatments. During the first half of the experiment, the performance of the populations is similar to that of the populations from RL-GT one level transfer experiments. After that time, improvement appears to level off. At the end the experiment, these populations have the lowest AMTQ among all treatments. Figure 8 shows the MTQ distribution for all treatments in the GT environment. The difference between between AMTQ values for the treatments is statistically significant (Kruskal-Wallis, p < 0.5).

ST-RL-CF-GT Waterfall Transfer. The ST-RL-CF-GT waterfall experiment has the second highest AMTQ values among all treatments in the GT environment (Figure 7). The ST-RL-CF-GT populations increase their AMTQ quickly at

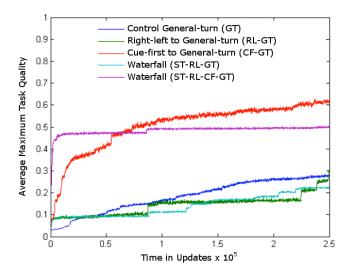

Figure 7: General-turn environment (GT), all treatments: ST-RL-GT waterfall experiments, ST-RL-CF-GT waterfall experiments, one level transfer experiments (RT-GT and CF-GT) and Control. The plot shows that the transferred CF-GT organism has the best AMTQ, while the ST-RL-GT has the lowest AMTQ among all treatments. The difference in AMTQ values between treatments was significant (Kruskal-Wallis test, p < 0.05).

the start of evolution, reaching an AMTQ above 0.4 with more than 90% of the experiment's time remaining. After the impressive start, however, improvement levels off, ending the experiment with an AMTQ value near 0.5 at the end of the experiment. Figure 8 shows the MTQ distributions from all treatments in the GT environment (Control, RL-GT, CF-GT, ST-RL-GT, and ST-RL-CF-GT). The difference between the MTQ distributions is significant (Kruskal-Wallis, p < 0.05). Table 2 gives a summary of the waterfall transfer experiments, showing the waterfall path (ST-RL-GT, or ST-RL-CF-GT) and the number of replicates that had MTQ value above 0.9. Similar to the one level transfer populations, the waterfall transfers from the CF environment had better MTQ, and a higher number of populations with MTQ value above 0.9.

Experiment	Replicates with MTQ > 0.9
ST-RL-GT	6
ST-RL-CF-GT	23

Table 2: Summary of waterfall transfer experiments, showing the waterfall path (ST-RL-GT, or ST-RL-CF-GT) and the number of replicates that had MTQ greater than 0.9. All 50 populations in each pathway survived to the end of the experiments in these treatments.

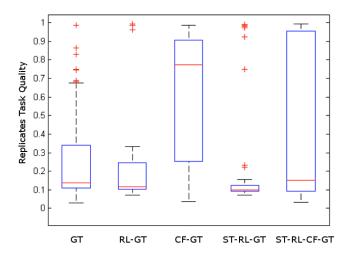

Figure 8: General-turn environment (GT), all treatments: ST-RL-GT waterfall experiments, ST-RL-CF-GT waterfall experiments, one level transfer experiments (RT-GT and CF-GT) and Control. Plot showing the distribution of MTQ values at the end of evolution for the different treatments. The difference in the MTQ values is significant (Kruskal-Wallis, p < 0.05).

Conclusions and Future Work

Our results provide mixed support for our hypothesis that earlier evolution will provide building blocks for evolving more complex functions. We observed strong effects of advantages bestowed by prior evolution in the one level ST-RL and CF-GT transfer experiments. From one perspective, these results are not surprising. Intuitively, some environments equipped organisms with more stepping stones toward the new environment than others. Organisms that evolved in the ST environment were exposed to both right and left turn environments over the course of evolution. Successful organisms would be able to react to both directional cues, providing an important advantage when transferred to RL environments. The critical ability that evolved in the CF environments was memory, the same fundamental capability that was needed for success in the GT environments. If organisms were capable of remembering past experience from the start of evolution in GT environments, evolution only needed to tinker with the use of memory to suit the details of the new environment. The RL environment did not provide this critical stepping stone required for success in the CF or GT environment. Success in RL environments required that organisms correctly recognize and react to the directional cues, with no memory needed. Thus, organisms that evolved initially in RL environments lacked the key memory ability needed for either the CF or GT environment.

We were initially somewhat puzzled by the lack of advan-

tage provided by earlier evolution in the waterfall transfer experiments. We suggest some possible explanations for the results. First, perhaps the other environments are too simple, and the differences in demands between environments are not pronounced enough to produce a significant effect. A second explanation is that the solutions that evolved earlier were not easily modified by more evolution. In other words, perhaps the solutions were not sufficiently evolvable. Both the lackluster performance of the transfer populations and the high mortality rate of one level transfer populations suggest that low evolvability may be an issue. The noticeably bad performance of the ST-RL-GT transfer populations reinforces this possible explanation. We have several avenues in mind for exploring this issue. We will do additional analysis on evolved genomes for evidence of overspecialization, such as high redundancy or large genomes. We will also analyze the structure and algorithms of selected evolved genomes to identify features that are tuned to a specific environment. Such tuning may be evidence for over-specialization. Experiments of long duration may also lead to a high degree of specialization or other factors that impact evolvability. For all three treatments, experiments were given a relatively long run time (250,000 Avida updates, around 10,000 generations on average). That length of time is more than enough for a particular solution to tune to the initial environment to such a degree that transferred organisms cannot survive the new environment. We plan to test this hypothesis with another series of experiments with shorter durations before transfers occur.

Another possible explanation for the waterfall transfer results is a bottleneck effect from using only the top five individuals as seeds for new populations. In addition to the loss of genetic diversity through the bottleneck, effects of random drift may be amplified. To counter these issues, we will do new experiments in which we seed new populations with an entire population from a prior environment.

The difference in survival rates between one level and waterfall transfers was also interesting. We plan to repeat our experiments while controlling the seed values used by Avida at the start of experiments, so that the waterfall transfer experiments use the same seed values as the one level transfer experiments. By doing this, we can test for whether the poor performance in the waterfall transfer experiments is related to bad luck in random seeds, or a more substantive effect.

We would also like to take the evolved genomes from the various experiments and analyze them in terms of information content, to provide a more quantitative view of the information required for these environments. Such analysis will help us to design improved environments and measurements for exploring the evolution of functional complexity.

Abstract

Within the context of evolution, an altruistic act that benefits the receiving individual at the expense of the acting individual is a puzzling phenomenon. An extreme form of altruism can be found in colicinogenic E. coli. These suicidal altruists explode, releasing colicins that kill unrelated individuals, which are not colicin resistant. By committing suicide, the altruist makes it more likely that its kin will have less competition. The benefits of this strategy rely on the number of competitors and kin nearby. If the organism explodes at an inopportune time, the suicidal act may not harm any competitors. Communication could enable organisms to act altruistically when environmental conditions suggest that that strategy would be most beneficial. Quorum sensing is a form of communication in which bacteria produce a protein and gauge the amount of that protein around them. Quorum sensing is one means by which bacteria sense the biotic factors around them and determine when to produce products, such as antibiotics, that influence competition. Suicidal altruists could use quorum sensing to determine when exploding is most beneficial, but it is challenging to study the selective forces at work in microbes. To address these challenges, we use digital evolution (a form of experimental evolution that uses self-replicating computer programs as organisms) to investigate the effects of enabling altruistic organisms to communicate via quorum sensing. We found that quorumsensing altruists killed a greater number of competitors per explosion, winning competitions against non-communicative altruists. These findings indicate that quorum sensing could increase the beneficial effect of altruism and the suite of conditions under which it will evolve.

Introduction

An organism behaves altruistically when it performs an action that lowers its own fitness in order to increase the fitness of another organism (West et al., 2007). Altruistic organisms ranging from bacteria to humans are found frequently in nature (Chao and Levin, 1981; Bowles, 2006). We might expect that any altruistic genes should be selected against because the altruistic organism will have a lower fitness than a non-altruistic organism benefitting from an altruistic act (a "cheater"). A particularly challenging form of altruism to explain is suicidal altruism, where the altruistic organism dies to increase the fitness of other organisms (Velicer

et al., 2000; Khare et al., 2009). However, inclusive fitness theory and multi-level selection theory both describe conditions under which altruism—even suicidal altruism—can evolve (Traulsen, 2006; Hamilton, 1963). According to inclusive fitness theory, altruism is favored by selection when an organism's altruistic action directly benefits its kin, who are likely to share the same altruistic gene(s) (Khare et al., 2009). However, an open question is how do altruistic organisms know when to behave altruistically? For example, how do altruistic organisms know when their kin surround them and would benefit from their actions?

Under certain conditions, colicinogenic E. coli commit suicide to kill nearby competitors and thus free resources for their kin (Chao and Levin, 1981). Specifically, these E. coli stochastically produce a toxin until they explode. Once an E. coli explodes, the toxin is released, killing all surrounding organisms that are not resistant. Because the exploding organism's kin are usually resistant to the toxin, they survive the explosion and benefit from the decrease in surrounding competition for resources (Chao and Levin, 1981). However, the prevailing environmental conditions, such as the number of competitors and kin surrounding the altruistic organism, determine the benefits of the suicidal action. Specifically, when an organism explodes, it is possible that either competitors are not present (and thus the explosion does not affect the competition for resources) or kin are not nearby (and thus are unable to take advantage of the accessible resources). In both of these cases, the altruistic organism committed suicide without providing any benefit to its kin.

An organism that can communicate with constituents to gain information about its environment could potentially improve decisions regarding when to perform altruistic actions. Quorum sensing is a type of communication found in many species of bacteria (Diggle et al., 2007; Davies, 1998), whereby the bacteria can assess how many constituent organisms surround them. Quorum sensing involves an organism releasing a small amount of a signaling protein and gauging the amount of that same protein that has been released by other bacteria around it (Bassler, 2002). A number of organisms combine quorum sensing with antibiotic

production to strategically kill competitors (Chandler et al., 2012). In these situations, producing an antibiotic is an expensive action and requires the cooperation of other constituents to produce enough to harm competitors. If too few organisms are producing the antibiotic, the action is expensive and does not accrue any benefits. However, if the organisms achieve quorum and ensure that enough constituents are also producing the antibiotic, then it is likely they can harm or kill the competitor. Thus, quorum sensing is used to enable organisms to determine whether the environmental conditions are favorable to perform expensive and possibly altruistic acts.

In this study, we explore whether altruistic organisms that do not have access to information about their environment would benefit from quorum-sensing capabilities. While enabling colicinogenic E. coli to use quorum sensing would determine the benefit of such a strategy, the challenges involved with performing that experiment are numerous. They include the difficulty associated with evolving complex traits, such as quorum sensing and suicidal altruism, and the generation time of E. coli. To address these experimental challenges, we use Avida, a digital evolution system (Ofria and Wilke, 2004). Within Avida, computer programs ("digital organisms") self-replicate with a chance of mutation and compete for space within their environment. Avida has been used to study evolutionary topics such as division of labor (Goldsby et al., 2012) and the evolution of biological complexity (Lenski et al., 2003). Additionally, Avida has been used to study suicidal altruism (Goings et al., 2004) and quorum sensing (Beckmann and McKinley, 2009) in isolation, making it the ideal platform for evolution experiments that combine these two complex traits. In this study, we use digital organisms that explode based on stochastic factors and quorum-sensing information when available. When an organism explodes, it kills competitors, and thus behaves similarly to colicinogenic E. coli. We study whether such organisms will evolve to use quorum-sensing capabilities and whether these capabilities provide a competitive advantage against altruists who cannot communicate.

Related Work

Suicidal altruism and communication have been studied extensively in both organic and digital systems (Berngruber et al., 2013; Bordereau et al., 1997; Chao and Levin, 1981; Crespi, 2001; Davies, 1998; Diggle et al., 2007; Foster et al., 2006; Goings et al., 2004; Goldsby et al., 2012; Hamilton, 1964, 1963; Kerr et al., 2004). Using both types of systems, researchers have found strong evidence that the benefits from higher inclusive fitness enables the success of suicidal-altruism strategies (Chao and Levin, 1981; Goings et al., 2004; Berngruber et al., 2013; Bordereau et al., 1997; Crespi, 2001; Foster et al., 2006). Furthermore, studies in both organic and digital systems have found that cooperation mediated by quorum sensing can be a successful strategy in a

number of environments (Diggle et al., 2007; Davies, 1998). Here we discuss relevant studies surrounding the evolution of suicidal altruism and quorum sensing within organic and digital systems.

Within nature, suicidal altruistic acts are generally performed to increase the success of the altruistic organism's kin (Chao and Levin, 1981; Berngruber et al., 2013). For example, colicinogenic *E. coli* stochastically kill competitors in an explosion of toxins, thus the surviving colony members have less competition for resources (Chao and Levin, 1981). Additionally, in some species of *E. coli*, when a bacterium of *E. coli* carrying the suicide gene *Lit* is infected by a lytic phage, it may kill itself to prevent the spread of the pathogen to the rest of the colony (Berngruber et al., 2013).

There are a number of organisms that use quorum sensing to regulate altruistic behavior (Miller and Bassler, 2001; Dworkin and Kaiser, 1985; Chandler et al., 2012). For example, Myxococus xanthus is a bacterium that uses quorum sensing to detect cell density. When confronted with starvation, at high cell density this bacterium forms fruiting bodies (Miller and Bassler, 2001). For the fruiting body to be successful, the majority of organisms must lyse to form the stalk and only a small fraction of the organisms reproduce as spores (Dworkin and Kaiser, 1985). Additionally, a number of species of bacteria use quorum sensing to kill competitors with antibiotics (Chandler et al., 2012). Competitors only die once the amount of antibiotics in the environment reaches a certain concentration (Chandler et al., 2012). If the antibiotic that is produced is too diluted, competitors may become resistant to it. As such, the bacteria are most likely to succeed in harming the competitors if a group of them simultaneously produce the antibiotic. Quorum sensing is used to establish that such a group is present and available to produce the antibiotic.

Altruism and quorum sensing have previously been studied in digital systems as well. Goings et al. studied suicidal altruism modeled on the colicinogenic E. coli's behavior (Goings et al., 2004). They discovered that suicidal altruism could evolve in the Avida digital evolution platform, even though the organisms could not communicate with each other. Suicidal altruism was most likely to evolve in a structured environment, where an organism had a high probability of being surrounded by its kin, rather than in a well-mixed environment, where an organism's kin were distributed randomly. In a subsequent study investigating environmental factors that influence the evolution of altruism, we found that large population sizes and high mutation rates increased the evolution of suicidal altruism (Johnson et al., 2014a). Additionally, Beckmann et al. studied the evolution of quorum sensing in Avida (Beckmann and McKinley, 2009). They determined that digital organisms could evolve to use quorum sensing to suppress replication when population density reached a specific threshold. Furthermore, they established that organisms using quorum sens-

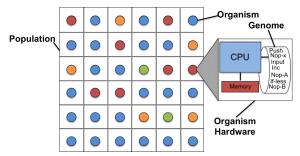

Figure 1: **An Avida population.** Each square represents a cell potentially occupied by an organism. Each circle represents an organism, where color denotes the genotype. Each organism consists of a genome, a virtual CPU for executing instructions, and memory space for storing values.

ing could utilize it within populations up to 400 times larger than those in which the organisms had evolved. While these studies explored the conditions under which suicidal altruism and quorum sensing arise independently, here we investigate whether the conjunction of these traits is beneficial.

Methods

For these experiments, we used the Avida digital evolution platform (Ofria and Wilke, 2004). Within Avida, digital organisms live on a toroidal grid where they compete for space (Figure 1). A digital organism consists of a computer program (its genome) and virtual hardware upon which the program is executed. Included in this virtual hardware are three registers that the organism can use to store and manipulate numbers. Each genome consists of a series of instructions that enable the organism to input numbers from and output numbers to the environment (IO), manipulate numbers, and self-replicate. Each organism occupies a specific cell in the grid. When an organism replicates, it creates two daughter organisms that inherit a potentially-mutated version of their parent's genome. One daughter organism replaces the parent and the other daughter organism is placed into a surrounding cell, potentially killing the current occupant.

Altruism and Quorum Sensing Instructions

For this study, in addition to the standard set of Avida instructions (Ofria and Wilke, 2004), we developed several instructions that enable organisms to evolve to use quorum sensing and altruistically explode (potentially killing competitors).

If evolved, the *quorum-sense* instruction enables the digital organism to sense how many related organisms surround it. For these experiments, we consider two organisms to be *related* if their genomes differ by three or fewer instructions. An organism's neighborhood consists of any organisms in the 5x5 grid surrounding the organism. When an organism executes the *quorum-sense* instruction, the following computation occurs: (1) The proportion of neighboring

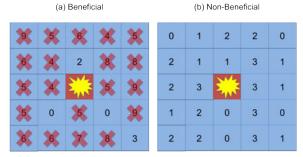

Figure 2: The results of an organism exploding in a beneficial and non-beneficial environment. Each 5x5 grid represents a subsection of the Avida world, where each square represents an organism. Within the grid, the center square represents the focal, exploding organism. The numbers specify the number of genomic differences from the focal organism. Squares containing an X represent organisms that are killed by the explosion because they are unrelated to the focal organism (i.e., they have four or more genomic differences). (a) This grid depicts the effects of a beneficial explosion. Many of the organisms surrounding the exploding organism are unrelated and are killed by the toxin released by the exploding organism. (b) This grid depicts the effects of a non-beneficial explosion. All the organisms in the exploding organism's neighborhood are related, thus the focal organism's explosion did not kill any competitors.

cells filled by related organisms is computed. (2) If this proportion is *less* than a *quorum-threshold* value specified by the organism, then one of the organism's registers is set to TRUE. While the organisms can use this capability in isolation, we envision that they will use it to assess whether environmental conditions are suitable for altruistic explosions.

The smart-explode instruction, if evolved, enables an organism to use quorum information in determining whether or not to explode. In many examples within nature, quorum sensing is used as a trigger for actions (e.g., a sufficient number of bacteria are present to produce an antibiotic). However, for this study, we envision that quorum sensing will be used to inhibit explosions under unsuitable conditions (Figure 2), though the population must still evolve to use the instruction in this way. Specifically, the presence of a quorum indicates that the focal organism is surrounded by related organisms and an explosion would not free up resources. As such, when the *smart-explode* instruction is executed, the following computation occurs (Figure 3): If the register specified by the organism (by default this is the same register that quorum-sense sets) is set to TRUE, the organism explodes with 5% probability. Otherwise, the instruction has no effect. The probability of exploding was 5% to be congruent with previous digital evolution studies (Goings et al., 2004).

Several factors influence whether organisms successfully make use of these instructions to sense their environment

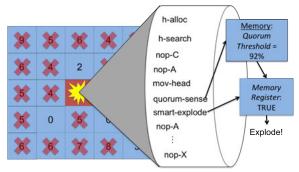

Figure 3: An organism executing the *quorum-sense* and *smart-explode* instructions. A portion of the genome and internal state of the exploding organism (exploding center square) are shown. When the organism executes the *quorum-sense* instruction, a register in the organism's memory is set to TRUE because the percentage of related individuals is less than 92% (the organism's quorum threshold). The organism then executes the *smart-explode* instruction, which checks the same register in memory and, because it is TRUE, explodes with a 5% chance.

and react accordingly. First, organisms are not able to directly sense the presence of competitors, but must infer this information from the proportion of related organisms around them. When an organism detects that only a few kin are in its neighborhood, it cannot be certain that the rest of its neighborhood contains competitors. Some or all of the nonkin cells could be empty spaces instead, rendering an explosion useless. This instruction mimics the quorum-sensing capabilities of natural organisms, who only sense the presence of conspecifics. Additionally, the register used by the smart-explode instruction can also be used by other instructions. An organism could have a suicidal-altruism strategy that does not use quorum sensing. The quorum-sense and smart-explode instructions provide the most accurate information when executed sequentially. This ensures that the organism is using the information gathered by the quorumsense instruction and that that information reflects the current status of the surrounding environment. For example, if an organism executes the quorum-sense instruction early within its lifetime, but waits to execute the smart-explode instruction until substantially later, then the quorum-sense information may no longer be accurate. This could result in an explosion that would not otherwise have occurred.

Experimental Parameters

For each treatment, we configured an environment in which organisms evolved on a 60x60 toroidal grid for 30,000 updates. An update is the time unit used by Avida. One update allows an organism to execute 30 instructions on average and 10 updates is approximately one generation. All experiments had a mutation rate of 0.02 genomic. These are standard parameters employed by Avida experiments (Go-

ings et al., 2004; Goldsby et al., 2012).

We performed two main types of experiments: single-lineage evolution and competition assays. The single-lineage evolution experiments started with one ancestor with a genome of length 100. The ancestor contained only instructions necessary for replication and no-operation (nop) instructions. In the quorum-sensing-altruists treatment of this experiment, the standard set of instructions and the *quorum-sense* and *smart-explode* instructions were available via mutation. In the non-quorum-sensing-altruists treatment (a control), the standard set of instructions and the *explode* instruction were available via mutation. When an organism executes the *explode* instruction, it explodes with a 5% probability.

To assess whether the *quorum-sense* and *smart-explode* instructions were undergoing positive selection, we compared how frequently they were executed to the frequency with which the *nop-Y* instruction was executed. *Nop-Y* is a no-operation instruction that does not affect the operation of the organism and therefore was used as a control.

We performed several competition assays with distinct starting proportions of the different lineages. For these experiments, the organisms were not able to mutate the quorum-sense, smart-explode or explode instructions in or out of their genome, which enabled us to assess the competitive capability of these lineages. The first set of competition assays started with a colony of non-quorum-sensing altruists and a colony of quorum-sensing altruists in equal proportions. The second set of experiments began with 95% non-quorum-sensing altruists and 5% quorum-sensing altruists. This permutation of initial conditions enabled us to test whether quorum-sensing altruists could invade a colony of non-quorum-sensing altruists. Finally, we determined if quorum-sensing altruists could repel non-quorum-sensing altruists by configuring the initial population to contain 5% non-quorum-sensing altruists and 95% quorum-sensing altruists.

Configuration files and data for all experiments are available at https://github.com/anyaejohnson/Communication14.

Results and Discussion

In this study, we first explore whether organisms will evolve to use quorum sensing to inform their decisions about when to behave altruistically. Next, we examine the strategies organisms evolved to determine how many related organisms constitute a quorum. Finally, we determine if organisms that can use quorum sensing to inform their decisions regarding if and when to altruistically commit suicide have a competitive advantage over organisms that do not have access to quorum-sensing information.

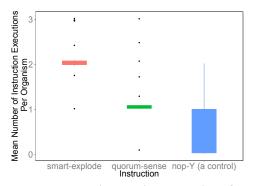

Figure 4: The average instruction executions for smart-explode, quorum-sense and a neutral instruction per organism in the population. The *smart-explode* instruction was used 1.95 more per organism than the neutral instruction (nop-Y) in the last 100 updates. The *quorum-sense* instruction was used 0.99 more per organism than the neutral instruction (nop-Y) in the last 100 updates (95% CI for difference between smart-explode and neutral instruction is 1.92 to 1.97 executions per organism, Wilcox rank sum test p < 0.0001; 95% CI difference *quorum-sense* instruction executions and neutral instruction is 0.96 to 1.00 executions per organism, Wilcox rank sum test p < 0.0001, error bars represent 95% confidence intervals). Both quorum sensing and suicidal altruism are under positive selection in this environment.

Can organisms evolve to use quorum information to decide when to commit suicide?

For our first experiment, we investigated whether quorumsensing and suicidal-altruism behaviors would evolve, rise in frequency, and ultimately stabilize in a population. To assess whether these capabilities were beneficial, we evolved a colony of organisms from an ancestor organism that could only reproduce, but quorum-sensing and suicidal-altruism instructions were available via mutation.

Figure 4 shows the execution rates per organism of the quorum-sensing, suicidal-altruism, and neutral instructions. In agreement with previous work (Goings et al., 2004), suicidal altruism was used an average of 1.95 time more frequently than a neutral instruction per organism by the final time point (median number suicidal-altruism instruction executions per organism = 2.00, neutral instruction executions per organism = 0.04, 95% confidence interval of difference is 1.92 to 1.97 instruction executions, Wilcox rank sum test p < 0.0001). Organisms also evolved to use the quorumsensing instruction an average of 0.99 more frequently than the neutral instruction per organism by the final time point (median number of quorum-sensing executions per organism = 1.03, neutral instruction executions = 0.04, 95% confidence interval of difference is 0.96 to 1.00 more instruction executions per organism, Wilcox rank sum test p < 0.0001). These results demonstrate that both suicidal-altruism and quorum-sensing capabilities were selected for.

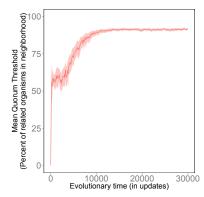

Figure 5: Mean quorum threshold evolved by quorum-sensing altruists. The quorum-sensing altruists evolved to use a *quorum threshold* of approximately 92% related organisms in their neighborhood. Within the context of this study, it is likely that an organism using quorum sensing would explode if its neighborhood contained 8% or more unrelated organisms or empty spaces.

How many related organisms constitute a quorum?

Quorum-sensing altruists are required to set a threshold to determine how many organisms constitute a quorum. This quorum threshold also implicitly sets the number of potential competitors or empty spaces that must be present for an explosion to be considered beneficial. For our quorum-sensing-altruist treatment, we explored how many organisms constituted a quorum by recording the value of the quorum threshold each time an organism exploded (once the exploding mechanism evolved into the population).

Figure 5 shows that the organisms evolved a median quorum threshold that corresponded to approximately 92% of the organisms around the focal organism being related (95% confidence interval is 91.29% to 92.63%). This percentage indicates that organisms using the quorum-sensing instruction with suicidal altruism would only probabilistically explode if one or more unrelated organisms or empty spaces were around the organism. This mechanism prevents the organism from exploding when the organism is completely surrounded by related organisms.

Is quorum information beneficial?

Ideally, an organism should use quorum sensing to assess whether its environmental conditions are such that an explosion would benefit its kin. However, the act of quorum sensing also has a cost: the organism must spend time gathering information about its environment. Within our study, this cost is experienced by the organism as the CPU cycles it devotes to gathering and using quorum-sensing information. To assess whether the costs of using quorum-sensing information outweigh the benefits of additional environmental information, we compared the behavior of quorum-sensing altruists to non-quorum-sensing altruists.

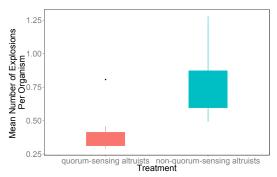

Figure 6: Mean number of explosions per organism for the quorum-sensing altruists and the non-quorum-sensing altruists. At the final time point in the treatments, the quorum-sensing altruists explode 0.35 less per organism on average than the non-quorum-sensing altruists (median quorum-sensing-altruist explosions = 0.35, median non-quorum-sensing-altruist explosions = 0.75, 95% CI for difference is 0.28 to 0.45 explosions per organism, Wilcox rank sum test p < 0.0001).

To investigate how these costs and benefits influence altruistic behavior, we determined the number of explosions per organism that occurred within the quorum-sensing-altruist and non-quorum-sensing-altruist treatments. Figure 6 shows the number of explosions per organism in each treatment. The quorum-sensing altruists explode an average of 0.35 times less frequently per organism than the non-quorum-sensing altruists (median quorum-sensing altruist explosions = 0.35, median non-quorum-sensing-altruist explosions = 0.75, 95% confidence interval of difference is 0.28 to 0.45 fewer explosions per organism, Wilcox rank sum test p < 0.0001). These results may indicate that quorum sensing allows the quorum-sensing altruists to avoid exploding in a detrimental environment or they may indicate that quorum sensing is not adaptive.

To assess whether quorum-sensing altruists are deriving more benefit from each explosion than non-quorumsensing altruists, we compared the mean number of organisms killed per explosion in each treatment. Figure 7 shows that the mean number of organisms killed per explosion by the quorum-sensing altruists and non-quorum-sensing altruists is 2.004 and 1.231, respectively. Thus, on average, the quorum-sensing altruists kill 0.702 more organisms per explosion than by the non-quorum-sensing altruists (95% confidence interval of difference is 0.567 to 0.847 organisms killed per explosion, Wilcox rank sum test p < 0.0001). The population size is also larger in the quorum-sensing-altruists treatment, which could be contributing to the greater number of organisms killed (median population size in the final time point of quorum-sensing-altruists treatment = 3423.5, non-quorum-sensing-altruists treatment = 3371.5). When the mean number of organisms killed is normalized by population size, the quorum-sensing altruists kill an average

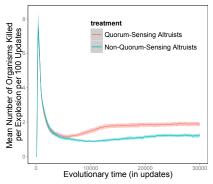

Figure 7: A comparison of the effects of quorum-sensing and non-quorum-sensing-altruist explosions. Shown is the average number of organisms killed per explosion every 100 updates. The quorum-sensing-altruist treatment is more efficient, killing 0.702 more organisms on average than the non-quorum-sensing altruists (mean number of organisms killed per explosion by quorum-sensing altruists = 2.004, mean number of organisms killed per explosion by nonquorum-sensing altruists = 1.231, 95% CI of difference is 0.567 to 0.847, Wilcox rank sum test p < 0.0001). We also calculated the average number of organisms killed per explosion normalized by population size. When normalized by population size, the average number of organisms killed per explosion by quorum-sensing altruists is 0.000197 more organisms than the non-quorum-sensing altruists (mean number of organisms killed per explosion normalized by population size for quorum-sensing altruists = 0.00058, nonquorum-sensing altruists = 0.00037, 95% CI of difference is 0.000161 to 0.000243, Wilcox rank sum test p < 0.0001).

of 0.000197 more organisms per explosion than the non-quorum-sensing altruists (mean number of organisms killed per explosion normalized by population size for quorum-sensing altruists = 0.00058, for non-quorum-sensing altruists = 0.00037, 95% confidence interval of difference is 0.000161 to 0.000243, Wilcox rank sum test p < 0.0001). Therefore, even when larger population size is accounted for, quorum-sensing altruists kill more competing organisms than the non-quorum-sensing altruists on average. These results suggest that the benefits of quorum sensing may outweigh the costs.

Does quorum sensing provide a competitive advantage for suicidal altruists?

We have demonstrated that quorum-sensing altruists kill more organisms per explosion than non-quorum-sensing altruists. However, these results do not yet demonstrate that quorum sensing provides a competitive advantage. While quorum-sensing altruists may kill more organisms per explosion, the costs of quorum sensing may yet outweigh this benefit. Therefore, we performed competition assays in which quorum-sensing altruists compete directly against

non-quorum-sensing altruists. Our competition assays used two lineages of organisms. One lineage was required to use the quorum-sensing-altruist strategy and the other lineage was required to use the non-quorum-sensing-altruist strategy. To focus on the competitive capabilities of these two strategies, we hand wrote both ancestor organisms and prevented the quorum-sensing and suicidal-altruism instructions from being accessible via mutation.

For our first competition assay, we filled half the population with copies of the quorum-sensing-altruist ancestor and the other half with copies of the non-quorum-sensing-altruist ancestor. Figure 8a shows the mean percent of organisms of each lineage over time. Out of 30 replicates, the quorum-sensing lineage fixed 30 times. Therefore, despite the additional costs of quorum sensing, the information gathered through quorum sensing provides a competitive advantage.

There are many situations in nature where a colony of organisms already exists. Therefore, we examined whether or not the quorum-sensing altruists could invade an existing population of non-quorum-sensing altruists. Specifically, we performed competition assays in which the lineage of quorum-sensing altruists started at only 5% of the population and the non-quorum-sensing altruists started at 95% of the population. As seen in Figure 8b, the quorum-sensing altruists were not able to invade a pre-established population of the non-quorum-sensing altruists and went extinct in 30/30 replicates.

Finally, we examined the reverse situation and explored whether quorum-sensing altruists could repel invading non-quorum-sensing altruists. Figure 8c depicts our results. In this case, the quorum-sensing altruists are able to repel the non-quorum-sensing altruists in all 30 replicates. These experiments demonstrate that quorum-sensing altruists have a competitive advantage over non-quorum-sensing altruists when they start at an equal or greater proportion of the population.

Conclusions

We explored whether organisms would evolve to use quorum sensing to inform a suicidal altruism strategy and whether such a strategy would have a competitive advantage. We found that when we enable digital organisms to set their own quorum threshold, they evolved a threshold of 92.1% on average, meaning that organisms evolved to require at least one competitor or empty space to be in their neighborhood in order to explode. Additionally, we found that quorum sensing increased the benefit of suicidal altruism (i.e., the number of competitors killed per explosion significantly increased). Finally, we found that quorum-sensing altruists outcompeted non-quorum-sensing altruists when starting at equal proportions or in the majority. Future work could explore intermediate values to address whether quorumsensing altruists could invade a pre-existing population. In further experiments, we also explored how the accuracy of

the quorum-sensing mechanisms affected their use (Johnson et al., 2014b). In general, quorum-sensing accuracy was correlated with an advantage in competitions against non-quorum-sensing altruists.

Suicidal altruism is a critical aspect of survival strategies in many natural systems, despite its high cost (Chao and Levin, 1981; Shorter and Rueppell, 2011). Communication has often been implicated as the element that might aid the evolution of altruism (West et al., 2007; Turner and Chao, 1999; Strassmann et al., 2011). This study offers support that: (1) Quorum-sensing capabilities can be used to make altruistic acts more effective. (2) Communicating altruists can outcompete altruists that are not able to communicate. In this study we purposefully kept the cost of quorum-sensing low to facilitate evolution. Future work could explore how increasing this cost affects the competitive advantage of quorum-sensing altruists.

Structured Populations with Limited Resources Exhibit Higher Rates of Complex Function Evolution

Abstract

The impact of population structure on evolving populations is difficult to study. Populations broken up into groups of organisms and connected by low levels of migration will experience different types of geneflow than normal unstructured populations. Various studies, spanning decades of research, have lead to seemingly contradictory conclusions. Some point to population structure as a means to improve adaptation, others argue that population structure hinders evolution. We investigate how population structure impacts the evolution of complex functions in environments with limited resources. We find that structured populations with limited resources tend to evolve complex functions at a higher rate than unstructured populations, across a broad range of migration rates. This suggests that population structure may have an important impact on evolution, in both sexual and asexual populations, at least at certain migration rates.

Introduction

Few topics in evolutionary biology have been as hotly debated as the impact of population structure (Moore and Tonsor 1994, Phillips 1996, Coyne et al. 1997, Wade and Goodnight 1998, Coyne et al. 2000, Goodnight and Wade 2000, Kryazhimskiy et al. 2012, Covert and Wilke 2014). Sewall Wright first suggested that populations structured into isolated subpopulations, connected with low levels of migration, created a balance between exploration of fitness landscapes and exploitation of fitness peaks (Wright 1932). According to Wright's theory, these structured populations could pass through fitness valleys that large unstructured populations could not.

Evolutionary computation researchers have relied on structured populations to improve the speed of evolutionary search, though little work has been done to determine if the improvement comes from a process similar to the one Wright envisioned, or some other source (Lin et al 1994, Belding 1995, Cantu-Paz 1998, Cantu-Paz 2001, Fernándex et al 2003). Meanwhile, the notion that structured populations may improve adaptation has proved controversial in evolutionary biology (Conye et al 1997, Coyne et al 2000), with many scientist arguing that populations structure may have no effect, or a negative effect on rates of adaptation (Kryazhimskiy 2012). Other studies have suggested that population structure may have a very important impact under

certain conditions (Moore and Tonsor 1994, Wade and Goodnight 1998, Goodnight and Wade 2000, Covert and Whilke 2014).

In structured populations, beneficial mutations take longer to sweep because they must wait for migration to carry them to every subpopulation. The longer a beneficial mutation takes to sweep, the greater the chance that a superior beneficial mutation will be discovered in one of the subpopulations that has not yet been swept yet. This process has been observed in large structured asexual populations and is referred to as leapfrogging (Gerrish and Lenski 1998, Miller et al 2011, Covert and Wilke 2014).

In a recent paper, Covert and Wilke (2014) demonstrated that at certain migration rates, leapfrogging from older genetic backgrounds yielded a dramatic fitness improvement. However, these experiments were asexual and did not address the impact of population structure in sexual populations. In addition, Covert and Wilke's experiments simulated populations with unlimited resources, which was a necessary simplifying assumption for their work, but is ultimately biologically unrealistic.

In this paper, we examine the impact of population structure in environments with limited resources. We run experiments with self-replicating digital organism that may reproduce asexually or sexually. We demonstrate that population structure improves the adaptive ability of populations, even when resources are limited, under both methods of reproduction.

Methods

We used Avida 2.12.2 (Ofria and Wilke 2004), to evolve self-replicating digital organisms, our complete experimental setup is free to download from git hub. Digital organisms are computer programs that exist on a grid. Each grid cell contains a virtual CPU and memory for the organisms to execute their code. During their lifetime each organism must copy every instruction in its genome into a new memory space and then execute a special "divide" command that places the new offspring in the environment. Single point mutations had a 25% probability of occurring on divide. All of our

populations were seeded with a hand-written ancestor 51 instructions long that could do nothing initially but copy itself.

All environments had nine logical functions that were rewarded in terms of increasing complexity and resource availability (Lenski et al 1999, Chow et al 2001, Covert et all 2012). Digital organisms could perform each of the nine logical functions by evolving a series of NAND operations. When a function was successfully performed the organisms' were rewarded only if there was sufficient resource in their current cell. When sufficient resources were present, they would be consumed by the execution of the function and the organism would be allowed to run its genome faster (Table 1). Rewards for each logical function were proportional to the number of NAND operations required to execute the function's most parsimonious configuration. Standard Avida populations have a difficult time evolving the most complex functions: XOR and EQU (Lenski et al. 2003, Covert et al 2012).

Function Name	Logic Operation	Speed Increase
NOT	~A; ~B	x2
NAND	~(A AND B)	x2
AND	A AND B	x4
OR_N	(A OR ~B) (~A OR B)	x4
OR	A OR B	x8
AND_N	(A AND ~B) (~A AND B)	x8
NOR	~A AND ~B	x16
XOR	(A AND ~B) OR (~A AND B)	x16
EQU	(A AND B) OR (~A AND ~B)	x32

Table 1 The standard nine logical functions in the Avida environment and their speed increases. Digital organisms have only the NAND operation in their instruction sets and must construct other logical functions out of NAND operations. The energy bonus for each function is equivalent to 2ⁿ, where n is the minimum number of NAND operations needed to complete it. In our experiments, each function reward was granted only if the organism was able to consume 1 unit of a limited resource.

We ran two experiments to test the effects structured populations with limited resources, one sexual experiment and one asexual experiment. Each experiment had 4 treatments, 3 in which the population was structured into 100 demes each with 100 organisms, and 1 that was a single large deme of 10,000 organisms. Each treatment had 40 replicates, seeded with the default ancestor and a unique random number seed.

Migration between demes occurred when digital organisms were born. Each population ran for 250,000 updates.¹

Each organism had a small probability of being placed in a different deme when it divided from its parent. Migration rates were selected based on previous results (Covert and Wilke 2014) indicating that the optimal migration rate was around 5x10⁻⁵ (one migration every other generation). We ran additional migration rates at one order of magnitude higher, 5x10⁻⁴ (5 migrants every generation) and one order of magnitude lower, 5x10⁻⁶ (one migrant every 20 generations).

In the first experiment, all organisms reproduced asexually, with offspring being placed in an adjacent grid cell. In the second experiment, all organisms reproduced via sexual recombination, similar to the recombination in Misivic et al (2006). In the sexual experiments, organisms copied their genomes and then placed their offspring into a "birth chamber". Each birth chamber was associated with the organism's deme. When an organism was placed in the birth chamber, it waited to be joined by a second offspring organism. When two organisms were present in the birth chamber, their genetic code was divided up into 5 regular segments, each segment had a 50% chance of being exchanged with the corresponding segment in the other genome. Finally the new organisms are placed in the population, adjacent to one of their parents. Each time a sexual organism is placed in the environment they undergo migration the same way asexual organisms do. Sexual organism being placed in the environment there is a small random probability that it will migrate different deme and be placed there.

We measured three main metrics in all experiments: fitness, genetic diversity, and how many complex functions evolved. Fitness was a ratio of total cpu speed up and the time an organism took to make a copy of itself. We recorded fitness of the most abundant genotype at the end of each experiment, this genotype is referred to as the final dominant. Diversity was measured in terms of Shannon information entropy on the number of genotypes in the population. This equation is given below (equ 1), where p_i is the proportion of the ith genotype in the population. Populations that had more genotypes have higher information entropy, populations with fewer genotypes have lower information entropy. Finally, we counted how frequently XOR and EQU, the two most complex functions (Lenski et al 1999, Lenski et al 2003), were performed. Unstructured populations of digital organisms with this size and mutation rate will only rarely evolve all nine logical functions (Covert et al 2013, Covert and Wilke 2014).

$$H(genotypes) = -\sum p_i \log_2 p_i \tag{1}$$

In all treatments resources were limited to an inflow of 10,000 units per update, distributed uniformly across the population so that each cell in the grid received one unit of resource. Each organism could use 1 unit of resource to perform one logical function during its life cycle. If no resource was

¹Updates are a unit of time in Avida. Each update the population executes 30 CPU cycles per living organism. CPU cycles are awarded based on how many logical functions the organism completes successfully.

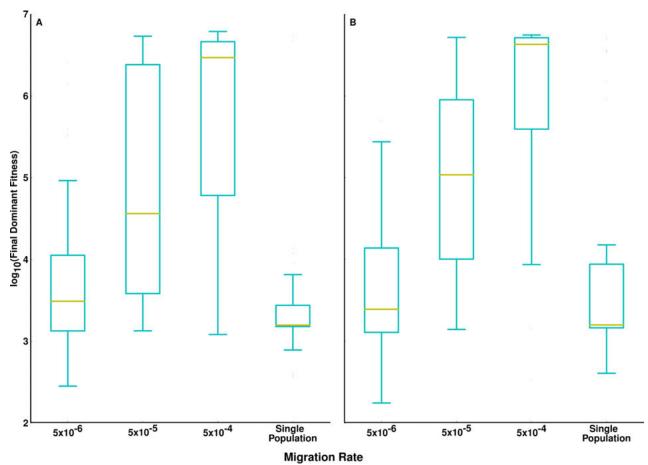

Figure 1 Log₁₀ Final dominant fitness at the end of each experiment for sexual (A) and asexual (B) experiments. All structured populations had higher median fitness than the single population controls. Differences in the $5x10^{-4}$ and $5x10^{-5}$ migration rates were significant, while the $5x10^{-6}$ migration rate was not significantly different from the control. See text for full statistical analysis.

available then no reward was granted for the function. Resources were spatially distributed such that each cell on the grid had its own pool of resource. Past works in Avida, have used globally distributed pools of resources (Chow et al 2006, Walker and Ofria 2012). Allocating resources to individual grid cells meant that organisms in different demes could not utilize the same pool of resources.

Results

Final dominant fitness from all treatments reveals a clear trend, in both sexual and asexual populations (Figure 1). At the highest migration rate, 5×10^{-4} , both sexual and asexual populations evolve higher fitness than in any other treatment (Figure 1), we refer to this migration rate as the optimal migration rate. Both sexual and asexual treatments have significantly higher fitness at the optimal migration rate (p < 0.05 and p < 0.001 respective Mann-Whitney U-test for comparisons with all other treatments).

Fitness remains elevated in the other structured populations, however only the 10^-5 migration rates was significantly

higher than the control populations (both p<0.05 Mann-Whitney U-test). As migration rate decreased, so did fitness, suggesting that genetic drift began to take over in the individual demes as geneflow decreased. This results is constant with pervious results in structured populations (Covert and Wilke 2014), however the range of optimal migration rates is larger here than was perviously observed.

We also measured genetic diversity, as a function of information entropy on the number of genotypes (see methods). Genetic diversity was inversely correlated with fitness in all of the structured populations, both asexual and sexual (Figure 2). Sexual structured populations had significantly higher genetic diversity than asexual populations (all p<0.001, Mann-Whitney U-test). The asexual unstructured population had no significant difference in diversity with the optimal migration rate (p=0.155, Mann-Whitney U-test), but lower migration rates had significantly higher diversity (p<0.01, Mann-Whitney U-test). However, the sexual unstructured population had higher diversity than the sexual structured populations (p<0.05, Mann-Whitney U-test). Despite increased genetic diversity, sexual populations were

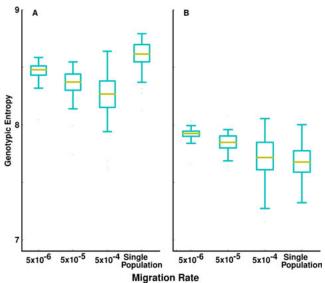

Figure 2 Genotypic entropy of the final population of sexual (A) and asexual (B) experiments. Structural populations had an inverse relationship with with migration rate. All sexual populations have significantly higher fitness than their asexual counter parts. The single population control had significantly higher diversity in the sexual case. The asexual control population had lower diversity or no significant difference in diversity from the asexual structured populations. See text for full statistical analysis.

unable to achieve higher fitness than their asexual counterparts, and the unstructured sexual population had lower fitness than all of structured treatments.

We measured how frequently the two most complex functions, XOR and EQU evolved in each treatment (Figure 3). Structured environments evolved complex function significantly more than the unstructured controls did (all p<0.001 Fisher's Exact test). Within just the structured treatments, asexual treatments at the two highest migration rates had no significant difference in the evolution of complex functions(XOR: p=0.79, EQU: p=1.0). The lowest asexual migration rate tested had fewer complex functions than the other two, but those differences were not significant (p=0.33 and p=0.55). The lowest asexual migration rate still evolved more complex function than the control (both p<0.05). Sexual structured populations followed a similar trend, with the two highest migration rates exhibiting high rates of task evolution and were not significantly different from one another (XOR: p=0.40, EQU: p=0.76). Even the lowest sexual migration rate produced more populations performing complex functions than the unstructured control.

While complex functions evolved at high rates over all migration rates, fitness remained relatively low at lower migration rates. This could indicate that high migration rates bring fit organisms to demes with pools of resources with greater frequency, keeping at least one subpopulation at high fitness at all times. Either way, structured populations had significantly improved evolution.

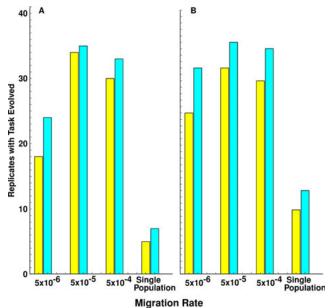

Figure 3 Complex function counts for all sexual (A) and asexual (B) treatments, showing the number of times of XOR (yellow) and EQU (cyan) evolved. All structured populations had significantly improved fitness over their controls. The lowest migration rate, $5x10^{-6}$, had significantly fewer complex functions than the higher migration rates, but was still significantly higher than the single population control in both the sexual and asexual cases. See text for full statistical analysis.

Discussion

Structured populations with limited resources demonstrate improved evolution over their unstructured counter parts. Both sexual and asexual structured populations exhibited improved fitness, genetic diversity and evolved more complex functions. Complex functions evolved frequently over a broad range of migration rates, even though resource limitations depressed overall fitness, particularly at lower migration rates.

Previous results in unlimited resource structured populations have shown an improved performance only at certain optimal migration rates (Covert and Wilke 2014). The optimal migration rate observed here was an order of magnitude higher than that of the previous study, indicating that the rate of resource inflow may determine which migration rate was optimal.

Other migration rates in unlimited environments were not significantly different from the control, or significantly lower than the control at very low migration rates. Structured populations evolved complex functions at a higher rate than the unstructured control, and at a broad range of migration rates. While overall fitness may be depressed due to a lack of resources, complex functions still evolved at a high rate. From this we may conclude that structured populations with limited resources are better able to adapt to their environment than

unstructured populations, or structured populations with unlimited resources.

Our populations with a simple structure and only a single limited resource evolved complex functions at extremely high rates. Evolving different complex functions in the same population is an extremely difficult problem, requiring organisms to maximize their evolutionary potential, while still exploiting already discovered fitness peaks. Evolutionary computation researchers have devised many ways of achieving this maximization through complex ecologies (Goings et al 2012) or through structured populations that impose artificial rules on migration between subpopulations (Hu et al 2005). Our results suggest that a balance between exploration and exploitation may be achieved by mirroring relatively straightforward structures and resource distributions inspired by natural systems.

These results could be altered by a number of factors. Lower resource inflow rates could result in reduced evolution. Here we ensured that every organisms could get rewarded for at least one function execution every update. At lower resource inflow rates selective pressure for complex functions would be reduced because rewards for evolving complex functions would become increasingly rare. At higher resource inflow rates populations would begin to evolve more like populations with infinite resources. Our work indicates that there is a range of optimal inflow rates, where a broad range of migration rates gives a distinct advantage to structured populations over unstructured populations.

Overall, structured populations are better able to adapt to limited resource environments than unstructured populations. This effect is detectable at a large range of migration rates and clearly indicates that resource limitation can dramatically improve evolutionary search in structured populations. This result addresses a long standing controversy in evolutionary biology, indicating that structured populations spread out over a large range may have improved adaptive ability. In addition, it provides further insight into methods that could be used to address difficult problems in computational evolution.

Extended Abstract

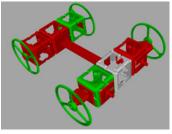

Science instructors from a wide range of disciplines agree that hands-on laboratory components of courses are pedagogically necessary (Freedman, 1997). However, certain shortcomings of current laboratory exercises have been pointed out by several authors (Mataric, 2004; Hofstein and Lunetta, 2004). The overarching theme of these analyses is that hands-on components of courses tend to be formulaic, closed-ended, and at times outdated. To address these issues, we envision a novel platform that is not only a didactic tool but is also an experimental testbed for users to play with different ideas in evolutionary robotics (Nolfi and Floreano, 2000), neural networks, physical simulation, 3D printing, mechanical assembly, and embedded processing.

Here, we introduce RoboGenTM: an open-source software and hardware platform designed for the joint evolution of robot morphologies and controllers a la Sims (1994); Lipson and Pollack (2000); Bongard and Pfeifer (2003). Robo-Gen has been designed specifically to allow evolved robots to be easily manufactured via widely available desktop 3D-printers¹, and the use of simple, open-source, low-cost, off-the-shelf electronic components. RoboGen features an evolution engine complete with a physics simulator, as well as utilities both for generating design files of body components for 3D printing, and for compiling neural-network controllers to run on an Arduino microcontroller board².

In this paper, we describe the RoboGen platform, and provide some metrics to assess the success of using it as the hands-on component of a masters-level bio-inspired artificial intelligence course.

Software Suite

The RoboGen software suite is comprised of two main components: an evolution engine that generates and reproduces robots, and a simulator that renders the evolutionary environment and assesses the fitness of the evolved solutions. Users may go from serial fitness evaluations (using a single

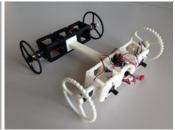

Figure 1: Sample robot evolved with RoboGen: simulation (left) and reality (right).

simulator) to massive parallelism distributed across a network depending on their computational resources.

Robot bodies Robots evolved with RoboGen (see Fig. 1) are composed of predefined and parameterized modules, and are represented as genetic programming trees (Koza, 1992). The modular building blocks that make up the body representations include passive and active structural elements as well as sensing components. A full list of components, and their detailed specifications may be found on the RoboGen website http://www.robogen.org.

Robot brains The "brains" of the RoboGen robots are fully-connected, recurrent artificial neural networks. The robots can sense their environment through touch sensors, light sensors and a six degree-of-freedom inertial measurement unit (IMU). The number of sensors and actuators used in robots increase the complexity of the simulations, but their use may be necessary to evolve robots that are truly adapted to diverse tasks and environments.

In the classroom environment, we provide several scenarios for the students to explore the utility of various parameters and components of the software suite. Specifically, we aim to promote an understanding of how the tasks and environments affect the evolved morphologies (Auerbach and Bongard, 2014), and how allowed simulation complexity changes the adaptedness of the robots generated through the evolutionary process.

¹Such as the MakerBot Replicator 2x: http://store.makerbot.com/replicator2x

²http://www.arduino.cc

The complexity of simulations achievable with this software is entirely dependent on the user: beginners can familiarize themselves with new concepts in a more controlled way by evolving only the neural network controllers, whereas advanced users can work on the evolution engine to customize the evolutionary algorithm or simulator or even introduce new morphological building blocks. This openendedness is a major advantage of the platform and addresses the current concerns regarding science laboratory education (Mataric, 2004). Additionally, our software is also the first educational platform that provides the users with the ability to manufacture their own evolved robots. By allowing users to get completely immersed in the artificial evolution process, we hope to encourage users to think about real-life applicability of their simulations. Finally, we aim to foster collaborations among groups of students with different expertise by having them design evolutionary scenarios, carry out experiments, and test their evolved designs in hardware.

Teaching Assessment

Discerning whether RoboGen is indeed an effective tool for teaching evolutionary robotics requires an analytical approach. For this reason, we devised a measuring tool to get a sense of how well the students in our class meet the desired learning outcomes. In our teaching assessment we focus on a set of measurable learning outcomes that were defined based on the "Content, Skills and Values (CSV)" classification of learning outcomes (Carleton University, 2014). A brief questionnaire was prepared to be administered twice during the course: once after the first in-depth introduction to the RoboGen project (but before the students begin working on the project), and once at the end of the project. The purpose of this scheduling is to determine the improvement in the technical skills targeted in this course.

The evaluation questions fall under one of the aforementioned CSV categories, and are answered on a Likert scale from 1 to 5, with 5 being the strongest positive response (Likert, 1932). The first questionnaire saw 67% participation (53 students).

The psychosocial and environmental factors that influence learning will be measured through a separate questionnaire administered at the end of the course, determining both the students' perception of the classroom environment for learning and their "ideal" environment. This questionnaire is an adapted version of the Science Laboratory Environment Inventory tailored to suit the teaching environment of the course given at EPFL (Fraser et al., 1995).

Conclusions

Overall, we envision RoboGen as not only an effective platform for evolving the morphologies and controllers of manufacturable robots, but also a valuable educational tool. It is a system that should be attractive to researchers, hobbyists, educators and students alike. Going forward we hope to develop a worldwide community around RoboGen. Users will be able to discuss their experiences, share ideas, and contribute to the growth of the project by introducing new morphological building blocks, evolutionary scenarios, and educational exercises.

Collective Design of Robot Locomotion

Mark Wagy and Josh Bongard

University of Vermont, Burlington, VT 05401 mwagy@uvm.edu

Abstract

It has been shown that the collective action of non-experts can compete favorably with an individual expert or an optimization method on a given problem. However, the best method for organizing collective problem solving is still an open question. Using the domain of robotics, we examine whether cooperative search for design strategies is superior to individual search. We use a web-based robot simulation to determine whether groups of human users can leverage design intuition from others to focus search on relevant parts of a complex design space. We show that individuals that work cooperatively with the aid of a simple optimization algorithm are better able to improve the design of robot locomotion than if they were to work individually with the aid of the optimization algorithm. This result suggests that groups of designers may more effectively work in tandem with optimization algorithms than individuals working in isolation.

Introduction

There is a long history of humans interacting with computer systems to design software agents. In one of the most famous examples of interactive design of software agents, human users interacted with Dawkins' *Blind Watchmaker* to generate "biomorphs": increasingly lifelike beings that resulted from a process of interactive selection (Dawkins (1996)). However, there is little basis for groups of humans interacting to design software agents collaboratively.

We know that positive feedback within a collective can spread through the group and result in wider perceptual abilities than that of the individual (Couzin (2007)). These types of positive feedback or autocatalytic phenomena may result in behavior that outperforms what any single agent in a population could achieve. Anecdotally, we know that teamwork in an organization can result in creative approaches to problem solving and that the intelligence of a group cannot be predicted by the average intelligence of its individual members (Woolley et al. (2010)). So might a group working with an optimization algorithm collectively arrive at better performing designs than an individual would on their own? With this question in mind, we use a web-based platform for robot and behavior optimization to determine whether groups of human users can leverage

design intuition from others to focus search on promising regions of a complex design space.

In order for users to be able to easily communicate designs, we have adoped a means of communicating through a language of graphical symbols, which in some sense acts as a "visual programming language". Visual programming structures can result in better "closeness of mapping" than textual representations (Green and Petre (1996)). That is, visual languages map programming abstractions more directly to the domain that they are modeling. We exploited the intrinsic pattern recognition capabilities of humans in the experiments reported here by developing a visual language for robot configuration. Users 'wire' subsets of a robot's joints together using colored lines, which constrains those subsets to move in phase with one another. An underlying evolutionary optimization algorithm then optimizes the movements of the joints to produce locomotion. Subsequent visitors to the site can then ascertain promising areas of the search space by visually inspecting the wiring patterns created by others and contribute their own computer's time to those regions, or create new designs of their own.

Three main literatures informed the design of our experiment: interactive evolutionary algorithms, visual design languages, and collaborative problem solving.

Interactive Evolutionary Algorithms

A group of non-experts, even children, have been found capable of training robots to achieve complex movement. Lund et al. (1998) employed child subjects in a programming-free, interactive evolutionary robotics experiment to train artificial neural networks to produce interesting robot behaviors such as obstacle avoidance and line and wall following. Chernova et al. (2011) used multiplayer online games featuring simulated robot agents to train a Case-Based Reasoning system. The robots then interacted with humans in a physical environment similar to the web-based simulation in which they were trained. However, the focus of most crowdsourcing robotics studies has been on using individual human users to train robots.

Similarly, in studies involving interactive evolutionary robotics, problem solving primarily involved a single individual dedicated to each training instance (Lund and Miglino (1998), Lund et al. (1998), Dozier (2001)). There was a one-to-one relationship between the human interacting with a robot control algorithm, rather than a group of individuals collectively working toward developing better robot control. Typically the individual directly evaluated fitness of computer-generated designs. Takagi (1998) gives a broad overview of how interactive evolutionary computation has been used for engineering and creative domains, from the design of hearing aids to evaluation of 3D CG images. The designs tended to be evaluated by a single human interacting individually with an evolutionary computing process. Celis et al. (2013) demonstrated the use of interactive evolutionary algorithms in robot control to overcome local optima through demonstration. Also, Bongard and Hornby (2013) used human users to train a user model to avoid local optima in an interactive evolutionary algorithm for the control of robot movement. That work built on the user modeling approach to interactive evolutionary robotics pioneered in (Akrour et al. (2011)). Recent work on exploring the possibility of tapping into user creativity using interactive evolutionary algorithms can be seen in Kowaliw et al. (2012) and García-Valdez et al. (2013).

Visual Design Languages

A substantial challenge in collaborative design is effectively communicating complex concepts between members of a group. In order to allow members of a group to build upon prior knowledge and thus improve past designs, key concepts in the problem domain must be communicated through some form of *working memory*. Larkin (1989) suggested that the use of a diagram is a means for storing problem states in a working memory. With this idea in mind, we developed a simple visual language of symbols for robot joint configuration. Users working together use these symbols as a blackboard system (Nii (1986)) to "exchange" ideas and improve the robot design.

Simplification of robot control by defining domain-specific languages is common in the robotics literature. For example, Peterson et al. (1999) define a declarative language for controlling robot behavior. Their framework is also focused on defining robust robot control rather than performing a single task such as fast locomotion. Cox and Smedley (1998), Cox et al. (1998) and Pfeiffer Jr (1998) all successfully employed visual programming languages for robot control. However, in the present work we are using symbols as a means of indirectly constraining the evolution of high-level robot behavior, rather than programming specific responses of the robot to its environment. It is not

the intent of our study to be able to train a robot to exhibit complex behavior with our symbolic cues. Rather, the symbols that represent different classes of robot movement act as a means by which to communicate possible unexplored parts of the evolutionary search space to others. Though in both cases, the importance of the direct mapping of visual indicators to the movement of robots is noted as an important benefit of visual over textual representations of a complex problem such as robot control.

Collaborative Problem Solving

Much of crowdsourcing work is focused on taking a large problem and dividing it into independent "microtasks" to be implemented by independent web-based workers. However, one of the most visible platforms for crowdsourcing is a collaborative one. The crowdsourced online encyclopedia Wikipedia 1 is one of the best examples of the success of collaborative human computing. Collaborative, networked design tasks have also shown promise in past literature. Kan et al. (2001) deployed a virtual reality framework in which the users of the system directly work with each other on product design. This contrasts with the present work in which individuals in the experimental group only indirectly collaborate with each other through the sharing of past designs asynchronously, but without the intent to directly work with each other. Users implicitly work towards a common goal, without directly working together (Doan et al. (2011)), similar to the approach described in (Von Ahn and Dabbish (2004)). Collaborative crowdsourcing of design tasks with an evolutionary computing backbone has also been explored in past work. Yu and Nickerson (2011) crowdsourced selection and recombination in an evolutionary process of designing alarm clocks. shared drawings of alarm clocks among Mechanical Turk workers to iteratively vet more creative and practical designs through a process of drawing combination. They show a significant improvement in the practicality and creativity of designs at the third generation versus the initial designs. The Picbreeder system developed by Secretan et al. (2011) employed a web-based collaborative system to create realistic images using the NEAT algorithm (Stanley and Miikkulainen (2004)). In this paper we investigate whether such collaborative dynamics can be brought to bear on robot design.

Methodology

We deployed a web-based platform (see Figure 1 for a screenshot) in which users "design" different robots, and then an evolutionary optimization algorithm evolves behaviors for them. Users were partitioned into control and

¹www.wikipedia.org

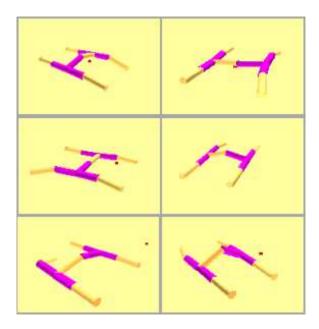

Figure 2: Screenshots the of robot.

experimental groups: those in the control group could not see robots designed by others, while those in the experimental group could. Each user's objective was to create robots that were most amenable to behavior optimization by the evolutionary algorithm. The specific behavior we investigated was legged locomotion.

Robot Form

The robot's form was fixed but users could constrain different subsets of joints to move in phase with one another. This process in essence reduces the dimensionality of the search space for the evolutionary algorithm, as it only has to optimize movements for each joint subset, rather than all joints independently. We henceforth refer to each such user-generated set of joint constraints as a robot design.

The robot's form consisted of ten cylindrical segments, connected with nine hinge joints. The robot had four legs, each with both a "shoulder" joint and an "elbow" joint. Each of the four legs were connected to a "spine" (see Figure 2 for screenshots of robot). The hinge joints could sweep through a range of $[-45^{\circ}, 45^{\circ}]$. The "shoulder" joints rotated the legs through the transverse plane. The "elbow" and "spinal" joints rotated through the sagittal plane.

The robot did not contain any sensors: the evolutionary algorithm produced open-loop controllers for the robots. The robot joints were actuated using a displacement-control sinusoidal signal. This sinusoidal actuation resulted in several possible gaits, depending on the phase value of the

sinusoid that drove each joint. The evolutionary algorithm described below could alter the relative phase between joints, but not the frequency or amplitude. The frequency was set such that the robot typically exhibited 40 rotations of each joint per evaluation. The amplitude allowed each joint to reach just about to its maximum and minimum range. However, this range could be constrained by the momentum of the robot and its friction with the ground plane.

User Interaction

Using a graphical interface representing a top-view of the robot form, users drew lines that linked hinge joints at the robot legs and spine into a group. Each grouping of joints was assigned a distinct color, based on the user-drawn lines that visually linked the nodes representing leg or spine joints (e.g. see Design Panel in lower right corner of Figure 1). When users drew links between joints, they were forcing those joints to have the same phase offset of the sinusoidal control as all others in the joint group - i.e. the phase value in the sinusoidal displacement control signal was the same for all joints in a grouping. This visually-oriented, symbolic display of joint connections allowed for easy communication of intuition about movement of the robot. For example, a user might notice that connecting diagonal joints results in trotting. They may realize that connecting the joints of the front legs together, and connecting the joints of the back legs together produces a two-beat version of cantering. The lines connecting joint group configurations acted as a symbol language that was designed to support the inherent pattern recognition abilities of the humans interacting with the underlying machine learning algorithm.

The robot movement was simulated with the *JBullet*² physics simulation engine, a Java port of the *Bullet Physics Library*³. The user could design their joint grouping in an interactive drawing panel and then press the *Run* button to see a "heads up" or graphical display of robot movement simulated in the *simulation panel*.

The time allowed for each simulation was fixed at 20 seconds. Since there was some level of non-determinism in the simulation, we added *background runs* to increase the sample size for each of the grouping/phase configurations.

Each time a user clicked the "GO" button to launch a "heads up" run (an actual visual simulation of the robot movement), four other background runs with the same joint grouping design and the same associated phase offset values were run, which the user did not see. Fitness was set to the mean distance produced by these five runs. More background runs would have been preferable, but we were

Figure 1: Screenshot of web-based design tool. A description of how to use the tool is on the top with an arrow indicating that the ordering of designs is from best to worst. The red arrow below the designs indicates in real-time how the current robot compares to the historical designs displayed. The *GO* button runs a robot simulation and the *reset* button loads a random design. The lower left panel is where the visualization of the robot movement is displayed.

constrained by the need to maintain usability of the tool. Running multiple physics simulation processes at once required enough computing resources that more than four background runs might have degraded the user experience.

Collaborative and Partitioned Groups

When a user opened the application, they were randomly assigned to either a control or experimental group. In the experimental group, users were allowed to see a subset of at most ten past designs created by other users in the experimental group. The ten designs were chosen randomly. If they returned to the site, they would see a different set of ten random designs. Users in the control group were limited to seeing only their own past designs in the history panel. If they ran more than ten designs, ten of their past designs were randomly shown. Users assigned to the control group would remain in the control group even if they left the site and then returned later, and similarly for the experimental group. Since users were anonymous, this group assignment was enforced using their IP address. As such, if a user

were to use the platform from two different computers they could have been exposed to another group. The designs in the history panel were ranked from "worst" (left) to "best" (right) (by best average distance that was achieved for that particular design). The average distance moved by the robot with a given joint grouping was reported under that design. The number of times that particular design had been evaluated was reported above it. Users could use the designs in the history panel as inspiration for how best to improve on the designs and could contribute more runs to a particular design if they wished. They also had the option of generating a random design by clicking the Reset button and altering it into a new design of their making.

Evolutionary Algorithm

The initial values used for each joint group's phase-offset were randomly selected from a uniform distribution between zero and 2π radians. If a given design for a joint grouping was reused, a mutated version of the best past phase values was used in this new simulation. Mutation

was implemented by picking a new value for each grouping with a probability of 0.1. Thus, the optimization used a hill-climber algorithm in which fitness (mean distance) was the basis for drawing from the population of eligible individuals (those that matched a given joint grouping). This best individual was then mutated. The distance that the robot was able to achieve with a given joint grouping and phase offset combination was interpreted as the fitness for that set of phase offsets. When multiple designs were created, the system became a parallel hill climber. Each design corresponds to an individual hill climber, and when a user creates a design that was previously created by another user (or re-created a design she has already created herself), another iteration of that hill climber was executed. If a user created a new design, a new hill climber with an initially random set of phase offsets was assigned to that design. The search space was thus a combination of both the combinatorial design space of joint group configurations and the real-valued space of phase-angle values to assign to each of those joint groupings.

User Incentivization

In order to incentivize users to participate in this experiment - and maintain their continued interest in using it - a sliding pointer under the history panel was incorporated into the user interface. As the robot moved, its real-time distance was indicated by the sliding pointer relative to the visible historical designs in the history panel. This allowed the user to visualize how well their design performed relative to a subset of random past designs, either created by themselves (the control group) or their own and others' designs (the experimental group). A secondary function of the performance slider was to gamify (Deterding et al. (2011)) the platform. We hoped that the user would be motivated to either create new designs that outperformed past designs or provide additional computation to previous designs to improve on them. In short, the user was imbued with the sense that they were in direct competition with a subset of historical designs.

Results

A total of 57 anonymous volunteer users participated in the study via the web. The platform was advertised on online message board systems to attract participants. Participants were not financially rewarded for their participation. Of the users that volunteered, 31 were assigned to the control group and 26 were assigned to the experimental group. The control group ran the simulation a total of 529 times and the experimental group ran the simulation a total of 581 times (see Table 1).

A random sampling of designs created by users in

	Control	Experimental
Number of users	31	26
Number of runs	567	581
Number of designs	76	78

Table 1: User statistics

both the control and experimental groups can be seen in Figure 5. We aggregated the maximum distance values each user was able to achieve. These maximum values were collected per group: the control (n=31) and experimental (n=26). The distributions of the control and experimental group were tested for rejection of the null hypothesis. The null hypothesis in this case was that the events come from the same distribution - that there is no difference between users who worked collectively versus those that worked individually. Using the t-test to reject the null hypothesis under the assumption of normality, we found significant cause to reject the null hypothesis at the 0.05 alpha level (p-value of 0.0404). Testing for the rejection of the null hypothesis without the assumption of normality also gave significant cause to reject the null hypothesis at the $\alpha = 0.05$ significance level, using the non-parametric Wilcoxon Rank Sum test (p-value of 0.0415).

Boxplots of the two distributions can be seen in Figure 3.

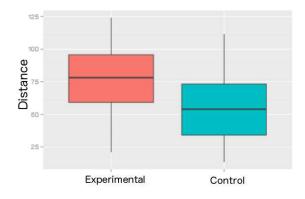

Figure 3: Distance distribution and p-values for significance between experimental and control groups. Significance tests: t-test p-value=0.0406, Wilcoxon Rank Sum p-value=0.0418.

Discussion

We have shown that the control and experimental groups are significantly different at the α level of 0.05. As such, we can say with some degree of confidence that the control and experimental groups are not drawn from the same distribution. That is, the maximum distances achieved by robots designed and optimized by those working collectively was

significantly different than the maximum distances of robots designed and optimized by those working individually. Furthermore, the largest distances achieved by the group working collectively were higher than those achieved by the group of individuals working alone. The experiment thus shows that working in a cooperative setting improved the overall search for better robot designs under these experimental settings.

These results could be a consequence of the fact that the experimental group was exposed to more total designs as a whole. When users of the experimental group first opened the platform, they were exposed to designs from past users (with the exception of the first user). However, exposure to past designs by other users does not necessarily imply that the experimental group has an advantage. The hill climber assigned to a given design may have been able to perform more iterations in the experimental group compared to the hill climber assigned to the same design in the control group, because multiple users in the experimental group may have contributed computational effort to that hill climber. However, this would only advantage the experimental group if this extra effort was directed toward an eventually successful design. Groupthink may have led users in the experimental group to contribute effort to one initially promising design, yet caused them to neglect a design that was less successful at the outset but may have yielded a superior controller in the long run.

It is also possible that the designs to which the experimental group were exposed informed their design decisions, which led to improved designs. Isolating the cause for improved designs in the experimental group will be pursued in future work.

Our experiment involved two embedded search spaces: 1) the combinatorial assignment of joints to phase-locked groups, and 2) the assigning of phase offsets to each group. The users directly searched the first, combinatorial space and the optimization algorithm searched the second, real-valued space. The interaction between the two search spaces may contributed to a stronger separation between the control and experimental groups. Additionally, the simulation of robot movement was not entirely deterministic; although there was a clear separation of mean distances achieved by different configurations. A plot of distributions of one hundred runs for several random configurations can be seen in 4. There is a clear separation of distributions between "good" (large distance traveled) versus "bad" (small distance traveled) configurations as to inform the user's intuition. And this non-determinism and large search space was present in both the control and experimental population so each group operated close to the same conditions.

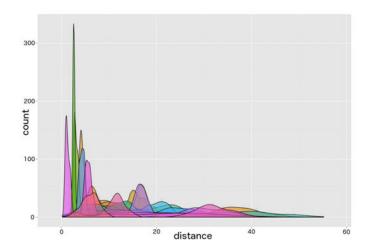

Figure 4: Distance distributions of robot movement for several joint group configurations. Each configuration was run 100 times.

As is common in web-based usage, a small minority of designs attract the majority of computation (Wilkinson (2008)). We can see in Figures 6 and 7 that more users focused their attempts on those designs that were able to move farther. That is, more users ran designs that were able to achieve higher distances in the experimental group; and more design evaluations were dedicated to higher fitness designs. Instead of focusing on designs that exhibited comical or low fitness behavior, users elected to add computing effort to promising, high fitness designs. Although there is not enough data to make definite conclusions about the possibility of "leap-frogging" (the tendency for users to draw inspiration from designs by other users to focus their efforts on promising designs) taking place in the experimental group, the data seem to suggest the possibility of positive feedback contributing to better performance when users worked collectively.

Using human subjects in evaluating fitness and developing new designs presents a number of challenges. When developing the platform, some effort was devoted to gamifying the system. The distance indicator was used to inspire the user to try and "beat" previous designs. Even though written instructions and the distance indicator were used to motivate the user to attempt to evaluate designs based on their ability to cause the virtual robot to move as far as possible, it is possible that users were either unmotivated by the preconceived goal of the simulation or had contrarian intentions to design robots that move as little or as comically as possible.

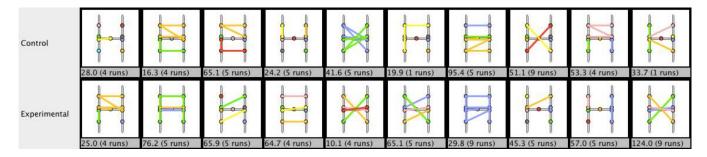

Figure 5: A random sample of designs created by users from the control and experimental groups, shown with best distance achieved and number of times a user evaluated that design (a "run").

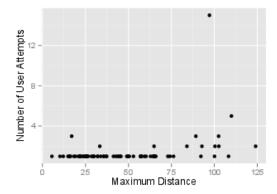

Figure 6: Each point corresponds to a design in the experimental group. The plot shows the number of users that attempted a unique design vs the best distance that that design achieved. Note that the design that received the most attention at 15 attempts was the "default" design that appeared when the application was launched in the user's web browser.

Conclusion and Future Work

We showed that in a hierarchical search space of robot designs in which human users searched the combinatorial level of the space and an optimization algorithm searched the real-valued level, a group that collectively searched the space was able to outperform a group of individuals that worked alone. The distributions of best robot distance achieved per person in each group were significantly different at an α level of 0.05 under both normal and non-parametric assumptions.

Using our framework, the user was shown the best distance that a given robot configuration moved as well as the number of runs contributed to each design. Novelty of a design might also be a useful message to communicate. Users might be incentivized to explore unknown regions of the search space if they were told that they came up with a design that no one else has tried. Additionally, the

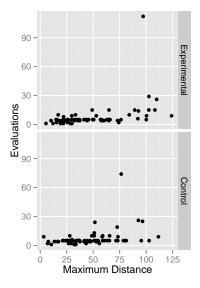

Figure 7: Number of evaluations for each design vs the maximum distance that design achieved. As is the case in Figure 6, the design that received the most evaluations was the "default" design that appeared when the application was launched in the user's web browser.

amount of symmetry in a given design or an indication of the spread of distances realized, such as standard deviation could be communicated. Social networks may be another means of incentivizing search: indicating which designs the user's friends have already explored could be built into the framework.

Another aspect of this work was the use of a symbolic language to easily communicate simple concepts of robot movement between human users. The language was so specific that it would only work with one form of robot. Future work on generalizing this language to quickly communicate complex ideas between collaborators may warrant further investigation.

Learning to Walk in Every Direction with the TBR-Learning algorithm

Antoine Cully^{1,2} and Jean-Baptiste Mouret^{1,2}

¹Sorbonne Universités, UPMC Univ Paris 06, UMR 722, ISIR, F-75005, Paris, France ²CNRS, UMR 7222, ISIR, F-75005, Paris, France mouret@isir.upmc.fr

Introduction

Legged robots are versatile machines that can outperform wheeled robots on rough terrain (Raibert, 1986), for instance in exploration or rescue missions. Their versatility is, however, tempered by their mechanical and control complexity, which makes them prone to mechanical damages and difficult to control robustly (Raibert, 1986; Bongard et al., 2006; Koos et al., 2013a). A promising way to compensate for these two weaknesses is to let robots discover *on their own* the best way to move in the current situation. A legged robot can thus cope with an unexpected terrain or with mechanical damages by learning a new walking gait (Bongard et al., 2006; Koos et al., 2013a), in the same way as animals can learn to limp with a sprained ankle.

Reinforcement learning (Kohl and Stone, 2004; Tedrake et al., 2005) and evolutionary algorithms (Zykov et al., 2004; Chernova and Veloso, 2004; Hornby et al., 2005) have been investigated to discover walking gaits for physical robots. Nevertheless, most of these investigations are limited to straight, forward walking, whereas a robot that only walks along a straight line is obviously unable to accomplish any mission. Only a handful of works deal with controllers able to turn or to change the walking speed. In these cases, controllers are successively evaluated on each possible direction (Mouret et al., 2006), or learned with an incremental process (Kodjabachian and Meyer, 1998). Compared to learning a simple controller, these two approaches significantly increase the learning time and the complexity of the search process.

In the present paper, we describe the Transferability-based Behavioral Repertoire Evolution (TBR-Evolution), a new learning algorithm that allows a robot to learn to walk in every direction in a single run of evolutionary algorithm. This algorithm combines the BR-Evolution algorithm (Cully and Mouret, 2013), which creates a behavioral repertoire in a single run, with the transferability approach (Koos et al., 2013b), which minimizes the number of evaluations on a physical robot when evolving controllers thanks to a simulator. A behavioral repertoire is a collection of simple controllers, where each of them reaches one position. An exter-

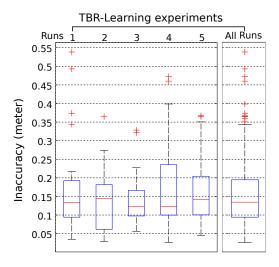

Figure 1: Inaccuracy of the controllers. The inaccuracy is measured as the distance between the endpoint reached by the *physical robot* and the one reached in simulation (30 repertoire's controllers are tested for each run). The results of the TBR-Evolution experiments are, for each run, separately pictured (Left) and also combined for an overall point of view (Right).

nal planing algorithm can thus successively pick up repertoire's controllers to generate a desired trajectory. Since TBR-Evolution does not depend on the controllers' architecture, it can be exploited in combination with most of the previous work about gait evolution.

Experiments

We evaluate the TBR-Evolution on a physical hexapod robot with 18 degrees of freedom (fig. 2B). The behaviors on the physical robot are assessed on-board thanks to a RGB-D sensor coupled with a state-of-the-art SLAM algorithm (Endres et al., 2012). For each TBR-Evolution experiment, a population of 100 solutions evolves during 3000 generations in simulation. After only 60 tests on the robot (one every 50 generations), the algorithm generates a collection with a

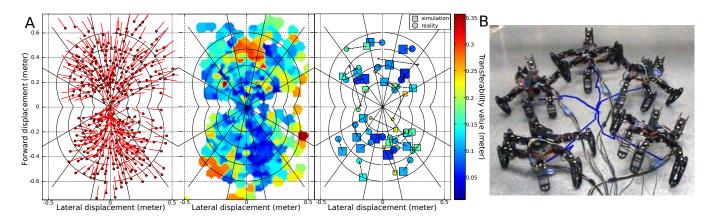

Figure 2: (A) Typical collection of controllers obtained with the TBR-Evolution algorithm. (Left) Endpoints in simulation of each controllers of the collection. The red lines are the final orientations of the robot. (Center) Estimated transferability map. The estimated transferability of each behavior of the collection is considered within a radius of 5 cm. (Right) Execution on the physical robot. we selected 30 controllers in the repertoire (square) and executed them on the physical robot (circles). The size and the color of the markers are proportional to their accuracy. (B) Illustration of 5 typical trajectories obtained with the TBR-Evolution.

median number of 375 controllers (min=353, max=394, five replications) allowing the robot to walk in every direction (fig. 2B). The periodical tests aim to drive the process to solutions that work similarly in simulation and in reality (i.e. crossing the reality gap, Koos et al. (2013b)). One of these collections is pictured in figure 2A.

The archive covers a large portion of the space around the robot (fig. 2A) and has an actual transferability value below 15 cm (difference between endpoints in the simulation and in reality. Fig. 1, left), which is consistent with the observations of the transferability map (Fig. 2, center) and not very large, taking into account the SLAM precision, the size of the robot and the looseness in the joints.

Investigating Modular Coupling of Morphology and Control with Digital Muscles

Jared M. Moore and Philip K. McKinley

Michigan State University, East Lansing, MI, USA 48824 moore112@msu.edu

Abstract

The musculoskeletal systems of animals are governed by a complex network of neurons that define both high- and lowlevel control. Individual joints are manipulated by multiple muscles acting as effectors for both movement and stabilization. We previously proposed a digital muscle model (DMM), where the morphological and control aspects of simulated joints evolve concurrently. The resulting solutions can provide insight into the evolution of natural organisms as well as possible designs for engineered systems. In this paper, we explore the integration of this model with an artificial neural network (ANN), focusing on the communication connections between the two. In the singly-connected strategy, a single ANN output is delivered to a joint; each constituent muscle responds to the signal according to an evolved function. In the individually-connected strategy, a unique ANN output is delivered to each simulated muscle. Results indicate that for low degree-of-freedom (DOF) robots, the individually-connected systems exhibit higher fitness than the singly-connnected systems. However, in larger DOF robots, the two strategies perform comparably, despite the fact that evolved ANNs for the singly-connected system are considerably simpler in terms of the number of connections in the network.

Introduction

Natural organisms demonstrate remarkable feats of locomotive agility, reaction, and maneuverability; the ability to run, jump, and accelerate has direct implications for survival. Complex neuromuscular and musculoskeletal systems underlie these abilities, which range from precise fine motor actions to purely strength based tasks (Gerritsen et al., 1998; Nishikawa et al., 2007). In nature, control and morphology evolve together. When applied to robots, this coevolutionary process has been effective in producing integrated controllers tuned to specific body configurations (Lipson and Pollack, 2000). Examples include bipedal locomotion (Paul and Bongard, 2001), gait development (Schramm et al., 2011), and wheeled robot navigation (Cliff et al., 1993). Typically, robotic joints comprise motor-driven actuators that receive commands directly from a high-level controller. In contrast, animal joints are composed of muscles, bones, and tendons that are tightly integrated with the somatic nervous system. Moreover, multiple muscles work together to control a single joint.

We previously developed a bioinspired abstract neuromuscular model called digital muscles (Moore and McKinley, 2014), which combines joint morphology and joint-level control. The orientation of muscle nodes around the joint, along with their (individual) responses to external signals, evolve concurrently. Evolving an abstract model has two major benefits. First, it is computationally efficient, enabling evolution of large populations over many generations. Second, the solutions discovered can be mapped into both detailed neuromuscular models of specific animals, providing insight into their evolution, as well as engineered joints based on motors. In addition, delegating aspects of control to the joint level potentially frees the high-level controller to focus on decision making. A set of evolutionary experiments with 3D animats demonstrated the evolution of effective gaits using only a simple sinusoid as the high-level control signal.

In this work we investigate combining this digital muscle model (DMM) with more complex high-level controllers, specifically, artificial neural networks (ANNs) evolved with the NEAT algorithm (Stanley and Miikkulainen, 2002). ANNs add a reactive control component that is not provided by the low-level DMM control framework. We explore two different approaches to interconnecting an ANN and a DMM-based joint: sending a common signal to all muscle nodes in the joint, or sending a separate signal to each muscle node in the joint. We refer to these configurations as *singly-connected* and *individually-connected*, respectively. Although the latter enables more fine-grained control of the joint, the number of ANN outputs increases rapidly with the complexity of the robot morphology.

Through a series of 10 treatments, we evaluate these two connection strategies in a ball balancing task and in the evolution of gaits for legged robots. We are particularly interested in how singly-connected systems, which enforce a modular coupling of ANN to DMM, thereby reducing the number of ANN outputs, perform against

individually-connected systems. Results show that in the ball balancing task, where the system has only a few joints, the individually-connected strategy outperforms the singly-connected strategy. However, in the quadruped and hexapod robot platforms, which have 8 and 12 joints respectively, the two control strategies perform comparably, despite the fact that the evolved ANNs in the singly-connected systems are considerably simpler, in terms of the number of connections in the networks. This result is consistent with theories of neural control in biological organisms where movement primitives in the spinal cord govern the coordination of multiple muscles (Giszter et al., 1993).

The contributions of this work are as follows. We first demonstrate a method to evolve aspects of control and morphology with an ANN and DMM. Second, evolved controllers exhibit effective behaviors with hybrid ANN/DMM controllers in two task environments. Third, this study provides insight into connection strategies between neural controllers and a digital muscle based joint-level control.

Background and Related Work

Evolutionary robotics (Floreano et al., 2008; Cliff et al., 1993; Nolfi and Floreano, 2000; Lipson, 2005) harnesses the process that has produced robust natural organisms and applies it to either physical or simulated robots. Evolved behaviors such as walking (Brooks, 1989), grasping (Bongard, 2010), and swimming (Sims, 1994) have been demonstrated. ANNs (Yao, 1999) are particularly amenable to evolutionary optimization, leading to effective locomotion in a robotic salamander (Ijspeert et al., 2005), bipeds (Reil and Husbands, 2002), and crawling robots (Inoue et al., 2007). Typically, these controllers produce high-level signals to govern the movement of each joint, such as specifying the desired angle of an actuator. In addition, a single controller often addresses multiple behaviors, from high-level decision making down to individual joint-level commands. In contrast, the movement of natural organisms is the result of complex interactions between an individual's neural and musculoskeletal systems (Wolpert and Ghahramani, 2000; Giszter et al., 1993).

This observation has led researchers to evolve morphology and control together. Bongard (2011) demonstrated the importance of morphology in the evolutionary process as a contributor to robustness in an individual. Embodiment (Pfeifer et al., 2007) of a controller within a morphology further emphasizes the coupled dynamics between the two. Paul and Bongard (2001) found that small changes to a robot's mass distribution have large effects on resultant gaits, leading to unique control/morphology pairs in evolved individuals. In this work, we investigate the joint-level coupling of morphology and control through the integration of ANN and DMM.

Simulated muscles have been investigated as effectors in a virtual robot platform by Lessin et al. (2013). Actuation occurs when a spring constant is changed, contracting the simulated muscle, subsequently moving the attached limbs. Geijtenbeek et al. (2013) demonstrated virtual muscle driven bipeds, capable of walking on both flat and varying surfaces. Muscles emulate physical properties defining attachment points, contraction paths, and actuation parameters determined through the optimization process. The gaits derived from this model feature realistic movements for the virtual creatures. These models emulate physical muscles directly in the simulated platform, whereas the proposed DMM does not consider muscles to be effectors modeled directly in a robot. Instead, the model focuses on the position and activation of muscles. This enables application of the DMM to motor based joints in traditional robots while contributing to the study of biological organisms.

Focusing on modularity in controller design may lead to more robust behaviors by introducing smaller, functional units for specific tasks (Pasemann et al., 2001; Brooks, 1986). Indeed, Doncieux and Meyer (2004) have shown that it may be difficult to develop complex control strategies without structural modularity in ANNs. Currently, modular approaches have focused primarily on the ANNs themselves. The DMM defines aspects of both morphology and control. In this paper, we investigate coupling strategies between ANN and DMM.

Digital Muscle Model

In (Moore and McKinley, 2014), we proposed the digital muscle model, a framework to model properties of physical muscles with the ability to map commands to conventional servo-driven robots. The DMM draws inspiration from natural organisms whose muscles provide the power necessary for movement. Working in antagonistic pairs, muscles facilitate flexion and extension of joints. Figure 1 shows a hinge joint controlled by a DMM muscle group.

Conceptually, the DMM organizes muscle *nodes*, analogous to biological muscles, into muscle groups at the joint level. The number of muscle nodes in a group is variable; in this study each muscle group consists of four muscle nodes. Each muscle node "contracts" in response to an input signal with the specific response determined by an internal activation function.

Muscle Node Structure. The position and activation of a digital muscle node govern its behavior. In this study, the activation function is a Gaussian with evolvable parameters: μ (center), σ^2 (spread) and α (magnitude). Similar to biological muscles, the nodes exert only contracting forces on the limbs. Direction of pull for a contracting node is determined by a node's position. The positions of nodes are evolvable, allowing for refinement of joint range of motion.

Calculation of Movement Commands. Figure 2 shows the activation functions of four nodes in a muscle group over

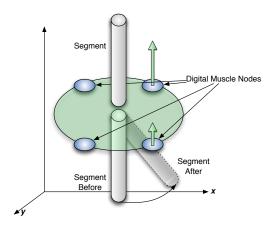

Figure 1: A joint in an animat is controlled by a muscle group comprising a set of muscle nodes. Each node is located on a 2D plane around the joint. When activated, nodes exert a pulling force on the limb segment, drawing it toward the node's position. Joint movement is calculated by aggregating the pulling forces of the muscle nodes.

the input range of [-1.0, 1.0]. Together with the positions of the four nodes, seen in Figure 1, they produce the commands seen in Figure 3. These two commands specify the movement of a single 2 DOF joint in the robot.

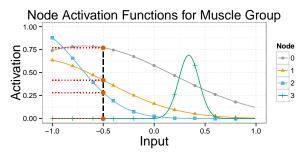

Figure 2: Activation functions of four nodes in a muscle group. At input value -0.5, the outputs correspond with the red circles intersecting the vertical line.

ANN/Muscle Model Integration. In our original study (Moore and McKinley, 2014), evolved quadrupeds exhibited successful gaits with DMM controllers, despite being driven by a simple sinusoidal signal. In this study, we connect the DMM to an ANN, creating a two-tiered control method. Figure 4 illustrates the two different strategies for connecting ANN to the DMM. The top figure shows the singly-connected strategy, where each muscle group is connected to one ANN output. The same ANN signal is passed to each node in a muscle group. Movement of the joint is then determined by aggregating the individual responses of each node to the signal. The bottom figure shows the individually-connected strategy, where each

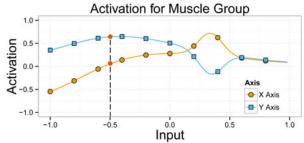

Figure 3: Joint movements are calculated by aggregating the activations and spatial position of each node in a muscle group. The activation functions from Figure 2 and spatial position of nodes seen in Figure 1 create the x and y axis outputs for a 2 DOF joint seen here. Nodes are positioned radially around a joint at 45°, 135°, 225°, and 315°.

node of a muscle group is connected to a unique ANN output. Here, the position and activation of a muscle node still determine its movement, but individual muscle nodes in a muscle group receive different commands from the ANN. Hence in this example, individually-connected ANNs require 4 times as many outputs as the singly-connected ANNs.

Methods

In this section we introduce specifics of ball balancing and gait evolution and discuss the evolutionary setup used in both tasks.

Ball Balancing Task. In the first task, an articulated platform is required to balance a ball dropped onto the center of the platform. Figure 5 shows the one-, two-, or three-segment arms with a platform at the top. The arm is affixed to the ground. Each joint has 2 DOF with $\pm 90^{\circ}$ of rotation on each axis. A ball is dropped from slightly above the platform to start a simulation. Upon contact with the platform, the ball is given a strong push in one of eight possible directions (N,NE,E,SE,S,SW,W,NW), attempting to knock it to the ground. Each simulation lasts for 20 seconds or until the ball contacts the ground. Fitness is assessed as the time interval between the ball's first contact with the platform and the last time of contact.

Six treatments are conducted in the ball balancing task. The first three treatments (A1,A2,A3) have singly-connected ANN/DMM controllers. Treatment A1 has a single joint connecting an arm segment to the platform. Treatment A2 adds an additional joint and arm segment, while the arm in Treatment A3 contains three joints. The other three treatments (B1,B2,B3) use individually-connected ANN/DMM configurations, with 1-, 2-, and 3-joint arms respectively. Each individual is evaluated in 5 environments randomly drawn from the 8 push directions mentioned previously. An

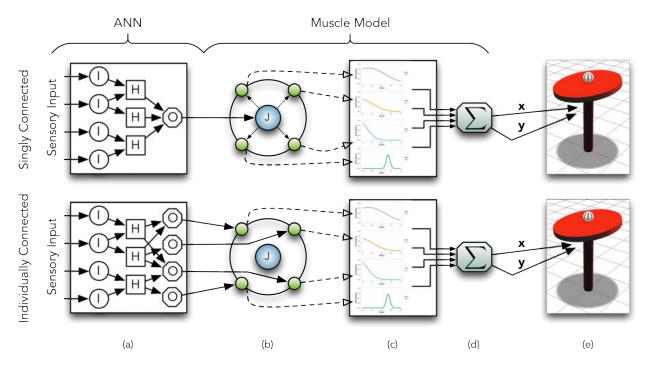

Figure 4: Examples illustrating the two connection strategies tested in this study: (top) singly-connected and (bottom) individually-connected. Interaction between the ANN and each DMM-based joint proceeds as follows: (a) The ANN receives input from sensors and produces output(s), 1 for a singly-connected joint and 4 for an individually-connected joint. (b) For a singly-connected joint, the same ANN output signal is distributed to each of 4 muscle nodes. For an individually connected joint, each muscle node receives its own signal directly from the ANN. (c) The position and activation function of each muscle node determines its response to the incoming signal. (d) The responses of the muscle nodes are aggregated and (e) passed to the platform.

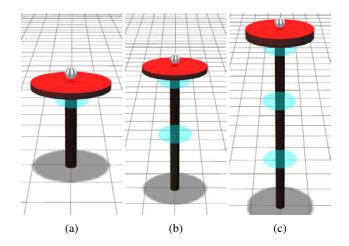

Figure 5: The platforms have either one, two or three actuated joints. Each joint is a 2 DOF hinge, allowing for pivoting on the x and z axes, with y being the radial axis of the arm. One joint connects the arm to the platform in each configuration with the others indicated by the transparent ellipsoids.

individual must react accordingly to the push, keeping the ball on the platform for as long as possible. Fitness is the average of the 5 simulations.

ANNs for the ball balancing task have nine to thirteen inputs. Three inputs represent the xyz distance between the platform and ball, including a sign to indicate direction, three represent the xyz linear velocity of the ball; a bias is also included. The final inputs comprise the relative angles [-1.0, 1.0] for the two axes in each 2 DOF joint. Inputs thus range from 9 to 13, depending on the number of arm segments in the platform.

Legged Gait Evolution. The second task applies the ANN/DMM to locomotion in legged robots. We conducted an additional four treatments (A8,B8,A12,B12) in an 8-joint quadruped and 12-joint hexapod to assess how modular connection strategies perform in higher DOF robots. Figure 6 shows the 8-joint quadruped robot and 12-joint hexapod robot used in this task. Two treatments (A8,A12) are conducted with singly-connected ANN/DMM controllers, and two treatments (B8,B12) with individually-connected ANN/DMM controllers. In Treatment A8, ANNs have 8 outputs, while in Treatment B8, the ANN has 32 outputs.

Accordingly, Treatment A12 has 12 outputs, and Treatment B12 has 48 outputs. Individuals are evaluated based on the total distance traveled in 10 seconds of simulation time on a high friction surface. Inputs to the ANN for both configurations include a sinusoidal signal, a bias, touch sensors for the feet, and 2 angle sensors per joint.

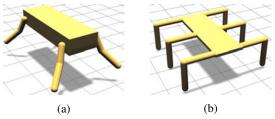

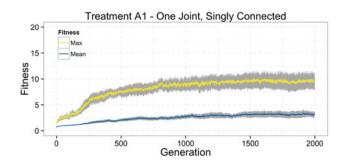

Figure 6: The digital quadruped (8 joints) and hexapod (12 joints) used in legged gait evolution. Each leg has two 2 DOF joints (hip and knee).

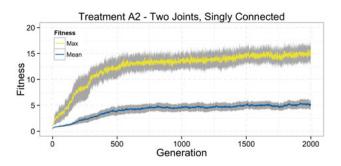

Evolutionary Setup. Populations comprise 100 individuals and are evolved for 2000 generations. We conduct 20 replicate runs per treatment, each with a unique starting seed. ANNs are evolved using the NEAT algorithm (Stanley and Miikkulainen, 2002). DMMs are paired with an ANN through a genome identifier. Thus, crossover between two DMMs is applied only when the two associated ANNs are recombined. Mutation is applied per generation to individual DMMs with a 5% chance per parameter; each joint has four nodes with four parameters each.

Results

Ball Balancing Performance. Figures 7 and 8 show the fitnesses of the 6 treatments from the ball balancing task. Here, fitnesses correspond to how long (seconds), on average, an individual balances the ball. Simulations last 20s. Treatments A1, A2, and A3 have varying success balancing the ball across replicates, however, no replicate run evolves an individual capable of balancing the ball for the full 20s in all 8 situations. Surprisingly, Treatment A3 fails to evolve any meaningful behavior. Apparently, the evolutionary process is unable to develop control strategies to coordinate the three joints.

In contrast, Treatments B1, B2, and B3 all produce effective behaviors, as shown in Figure 8. Furthermore, the population average fitnesses are also significantly higher than the singly-connected treatments. The evolutionary trajectories of the three treatments are similar, although it appears to take longer to evolve solutions for more joints. During validation against the full 8 push directions, all but 1 of the replicates from Treatment B1, every replicate in Treatment B2, and all but 2 replicates in Treatment B3 evolved individuals capable of handling all conditions.

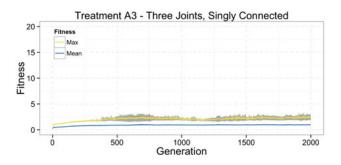

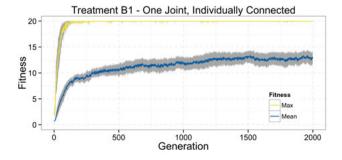

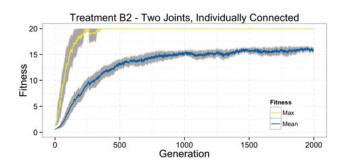

Figure 7: Mean fitnesses from 20 replicate runs for singly-connected individuals. Shaded regions represent 95% confidence intervals.

Evolved ANN Complexity. Figure 9 shows the relative complexity of the evolved ANNs for each of the treatments, defined as the number of connections between nodes in the ANNs. For Treatment A, the most effective networks arise in Treatment A2, which coincidentally have the highest ratio of performance to network size. Larger networks result in higher fitness values for Treatment A2. Conversely, Treatments B1, B2, and B3 all exhibit less complex networks. The connection strategy between ANN and DMM appears to be a key indicator of performance in this task. The singly-connected strategy is unable to evolve a solution capable of addressing all 8 push directions. Treatment B is able to address the task, with ANNs having individual connections to the muscle nodes. Presumably, this allows for finer control of the joints in these low DOF morphologies. Even with the

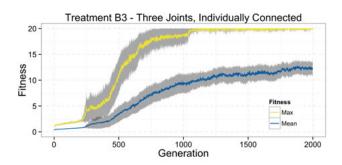

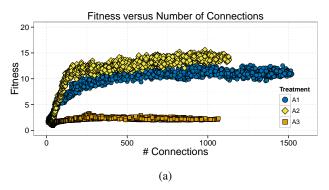

Figure 8: Mean fitnesses from 20 replicate runs for individually-connected individuals. Shaded regions represent 95% confidence intervals.

increased output space required in the ANNs of Treatment B, the number of connections in the best evolved networks is half that of Treatment A.

Apparently, this modular connection strategy in Treatment A necessitates the evolution of more complex networks in all three platform configurations. The reduced connectivity in Treatment A requires the evolution of coordination between muscle node activation functions for a single input signal from the ANN at the joint-level. Next, we investigate whether these results scale to legged robots with 8- and 12-joints.

Legged Gait Evolution. Figures 10a and 10b, respectively, plot the fitnesses for the quadruped and hexapod runs. Unlike the ball balancing task, individually-connected con-

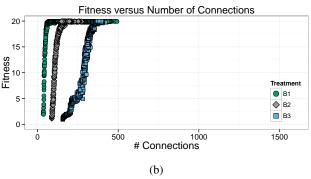

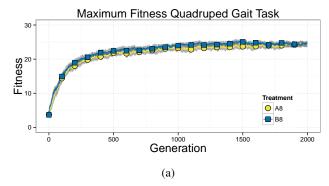

Figure 9: Number of connections between nodes in the ANN versus fitness across the treatments. (a) Evolved networks in Treatment A exhibit between 500 and 1500 connections in the top 10% of performers. (b) Evolved networks from Treatment B exhibit 100 and 500 connections in the top 10% of performers. In addition, the B treatments are all able to address the ball balancing task.

trollers in Treatment B8 only slightly outperform singlyconnected individuals in Treatment A8, with the 95% confidence intervals overlapping. Performance is nearly identical between Treatments A12 and B12. Figure 11 shows the difference in ANN complexity, with the singly-connected strategy producing less complex networks in contrast to the results seen in the ball balancing task. Figure 12 shows the resulting number of connections in the evolved ANNs for Treatments A12 and B12. In this case the network complexity further diverges, although both strategies exhibit effective walking gaits. That A treatments achieve performance similar to the B treatments, using less complex ANNs, suggests that the singly-connected strategy is an effective controller in these higher DOF robots. Reductions in network complexity become more important as the DOF in a robot increases. In robots with greater DOF, ANN complexity can impact controller performance, making compact networks more desirable.

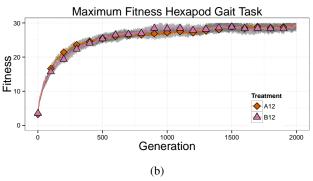

Figure 10: (a) The best performing individuals from Treatments A8 and B8 in a quadruped gait evolution task. (b) The best performing individuals from Treatments A12 and B12 in a hexapod gait evolution task. Each line represents the average of 20 replicate runs with shaded areas indicating 95% confidence intervals.

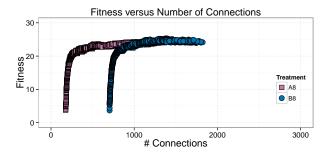

Figure 11: Number of connections between nodes in the ANN versus fitness for the quadruped platform. Here, the evolved ANNs for Treatment A8 are less complex than those of Treatment B8, even though performance is similar, suggesting that as the number of joints increases, a singly-connected control strategy performs comparably with a less complex ANN.

Conclusions

In biological organisms, multiple muscles cooperate to realize movement of joints. The digital muscle model provides a computationally efficient means to evolve joint-level con-

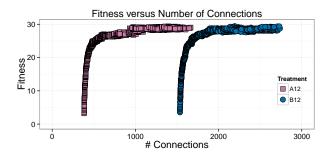

Figure 12: Number of connections between nodes in the ANN versus fitness for the hexapod platform. Evolved ANNs for Treatment A12 contain fewer connections than those of Treatment B12.

trol in 3D animats. The model captures fundamental properties of natural muscles while remaining abstract enough to apply to robotic joints. In this paper, we have examined the integration of a high-level ANN controller with low-level DMM-based joints to realize effective behavior in robots. In the ball balancing task, where the system has up to three joints, individually-connecting ANN outputs to muscle nodes produces higher fitness than singly-connected systems. When evolving gaits in the 8-joint quadruped, however, individually- and singly-connected ANN/DMM controllers perform comparably, with evolution producing considerably simpler ANNs in the latter case. Results for the 12-joint hexapod robot are similar, with even greater disparity in network complexity. In the future, we plan to investigate the coupling of these two strategies in higher DOF robots and for more complex tasks. In addition, we plan to investigate the effect of enforced symmetries and indirect mappings, which were intentionally left out in this work in order to focus on interaction between the ANN and DMM.

Abstract of: Fast Damage Recovery in Robotics with the T-Resilience Algorithm

Sylvain Koos^{1,2}, Antoine Cully^{1,2} and Jean-Baptiste Mouret^{1,2}

Sorbonne Universités, UPMC Univ Paris 06, UMR 722, ISIR, F-75005, Paris, France CNRS, UMR 7222, ISIR, F-75005, Paris, France mouret@isir.upmc.fr

Damage recovery is critical for autonomous robots that need to operate for a long time without assistance. Most current methods are complex and costly because they require anticipating each potential damage in order to have a contingency plan ready and diagnosis procedures.

An alternative line of thought is to *let the robot learn on its own* the best behavior for the current situation. If the learning process is open enough, then the robot should be able to discover new compensatory behaviors in situations that have not been foreseen by its designers. Classic reinforcement learning algorithms are hard to apply to low-level robotic problems (Togelius et al., 2009), but evolutionary algorithms (EAs) are good candidates to find original solutions because they can optimize in the continuous domain and work on the structure of controllers (e.g. neural networks).

When evolving controllers for robots, EAs are reported to require many hundreds of trials on the robot and to last from two to tens of hours (e.g. (Hornby et al., 2005; Yosinski et al., 2011)). These EAs spend most of their running time in evaluating the quality of controllers by testing them on the target robot. Since, contrary to simulation, reality cannot be sped up, their running time can only be improved by finding strategies to evaluate fewer candidate solutions on the robot.

By first learning a self-model for the robot, then evolving a controller with this simulation, Bongard et al. (Bongard et al., 2006) designed an algorithm for resilience that makes an important step in this direction. Nevertheless, this algorithm has a few important shortcomings. First, actions and models are undirected: the algorithm can "waste" a lot of time to improve parts of the self-model that are irrelevant for the task. Second, the diagnosis may be wrong, which leads to a useless contingency plan. Third, there is often a "reality gap" between a behavior learned in simulation and the same behavior on the target robot (Jakobi et al., 1995), but nothing is included in Bongard's algorithm to prevent such gap to happen: the controller learned in the simulation may not work well on the real robot, even if the self-model is accurate.

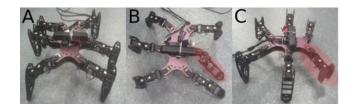

Figure 1: (A) The hexapod robot is not damaged. (B) The left middle leg is no longer powered. (C) The terminal part of the front right leg is shortened by half.

Our algorithm is inspired by the "transferability approach" (Koos et al., 2013b), whose original purpose is to cross the "reality gap" that separates behaviors optimized in simulation to those observed on the target robot. The main proposition of this approach is to make the optimization algorithm aware of the limits of the simulation. To this end, a few controllers are transferred during the optimization and a regression algorithm (here a SVM) is used to approximate the function that maps behaviors in simulation to the difference of performance between simulation and reality. To use this approximated transferability function, the singleobjective optimization problem is transformed into a multiobjective optimization in which both performance in simulation and transferability are maximized. This optimization is performed with a a multi-objective evolutionary algorithm (NSGA-II, Deb et al. (2002)).

The same concepts can be applied to design a fast adaptation algorithm for resilient robotics, leading to a new algorithm that we called "T-Resilience" (for Transferability-based resilience). If a damaged robot embeds a simulation of itself, then behaviors that rely on damaged parts will not be transferable: they will perform very differently in the self-model and in reality. During the adaptation process, the robot will thus create an approximated transferability function that classifies behaviors as "working as expected" and "not working as expected". Hence the robot will possess an "intuition" of the damages but it will not explicitly represent or identify them. By optimizing both the transferability and

This paper is an extended abstract of Koos et al. (2013a).

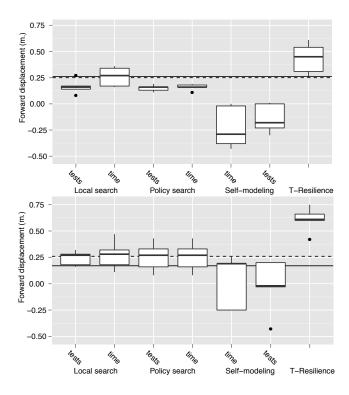

Figure 2: Performances (distance covered in 3 seconds) obtained in case B (top) and C (bottom). On each box, Each algorithm has been run 5 times and distances are measured using the external motion capture system. Except for the T-Resilience, the performance of the controllers found after about 25 transfers (tests) and after about 20 minutes (time) are depicted (all T-Resilience experiments last about 20 minutes and use 25 transfers). The horizontal lines denote the performances of the reference gait, according to the external (dashed line) and to the internal (solid line) measurement.

the performance, the algorithm will look for the most efficient behaviors among those that only use the reliable parts of the robots. The robot will thus be able to sustain a functioning behavior when damage occurs by learning to avoid behaviors that it is unable to achieve in the real world. Besides this damage recovery scenario, the T-Resilience algorithm opens a new class of adaptation algorithms that transfers most of the adaptation time from real experiments to simulations of a self-model.

Experiments

We evaluate the T-Resilience algorithm on an 18-DOFs hexapod robot that needs to adapt to motor failures and broken legs (figure 1); we compare it to stochastic local search (Hoos and Stützle, 2005), policy gradient (Kohl and Stone, 2004) and Bongard's algorithm (Bongard et al., 2006). The behavior on the real robot is assessed on-board thanks to a RGB-D sensor coupled with a state-of-the-art SLAM algorithm (Endres et al., 2012). For each experi-

ment, a population of 100 controllers is optimized for 1000 generations. Every 40 generations, a controller is randomly selected in the population and transferred on the robot.

Using only 25 tests on the robot and an overall running time of less than one hour on a recent laptop, T-Resilience consistently leads to substantially better results than the other approaches (figure 2).

Abstract

This is an extended abstract of a recent PLoS ONE paper (Haasdijk et al., 2014) in which we introduce the MONEE paradigm as a method of combining open-ended (to deal with the environment) and task-driven (to satisfy user demands) adaptation of robot controllers through evolution.

Introduction

Evolutionary Robotics is concerned with the use of Evolutionary Algorithms to develop robot controllers and sometimes robotic hardware. The majority of related work is inherently goal-driven and uses evolution to optimise task performance of the robots for some clearly defined set of tasks. A few papers have investigated a more ALife flavoured approach where evolution is environment-driven, i.e., the chances for reproduction and survival are not based on user defined task performance.

In recent works, we argued that balancing evolution between environment-driven adaptation and task-driven optimisation is essential for self-sufficient robot collectives in environments where human supervision is impossible, too expensive, or limited. To implement such a combination, we recently introduced an algorithmic framework dubbed Monee (Multi-Objective aNd open-Ended Evolution) (Haasdijk et al., 2014). The main idea is to exploit the fact that evolutionary methods have two basic selection mechanisms and to use these in different roles: survivor selection driven by the environment and parent selection based on task-performance.

In the following, we review briefly the mechanisms at work in MONEE, and provide evidence that it can actually perform adaptation to the environment *and* objective-driven evolutionary optimisation.

MONEE

The proof of concept for MONEE is based on mEDEA—an ALife flavoured system introduced by Bredeche et al. (2012). In this system, robot controllers evolve without an explicit fitness measure in a distributed fashion, i.e., without a central 'oracle' orchestrating selection and reproduction. Robot controllers can procreate by transmitting their

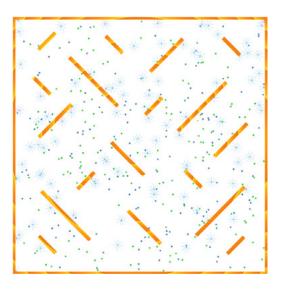

Figure 1: **Experiment screenshot.** Robots are shown as small circles with sensor beams indicated. Pucks are shown as small blue and green squares. The shaded orange rectangles indicate arena walls and obstacles.

genome to other robots directly. However, sending and receiving genomes are regulated by distinguishing two phases in each robots lifecycle.

- **Life phase**: robots controllers have a fixed lifetime during which they perform their actions; moving about, foraging, and sending around their genomes.
- Rebirth phase: when its lifetime ends, a robot enters the rebirth phase and becomes an 'egg': a stationary receptacle for genomes that are transmitted by passing live robots. This rebirth phase also lasts a fixed amount of time, and once this has passed, the egg selects parents from the received genomes to create a new controller. The robot then reverts to the 'life' role with this new controller

Note that the more eggs a robot inseminates, the more chances it has for procreation. Experiments with mEDEA

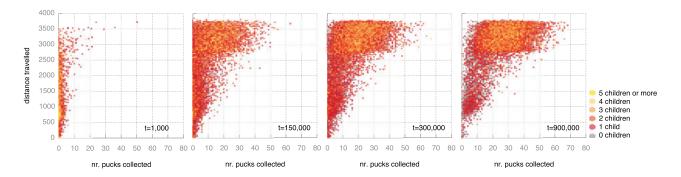

Figure 2: **Offspring count vs distance travelled and number of pucks collected.** From left to right, plots shown for time intervals at 1,000, 150,000, 300,000 and 900,000 ticks. Initially, distance travelled and number of pucks collected have little influence on an individual's fecundity. As time progresses, the influence of travelling distances and collecting pucks becomes progressively pronounced.

demonstrated a trend towards increased mobility as an evolutionary response to these environmental conditions.

MONEE adds task-driven parent selection by considering credits amassed by robots when they perform tasks (e.g. a gathering task in our experiments). When a robot inseminates an egg, it passes the current credit counts along with the genome and the egg uses that information to select parents when it revives, reminiscent of parental investment schemes (although a parent does not actually invest when impregnating an egg because the credits are not *transferred* but *copied*, at no cost to the parent). Thus, the credits relate task performance to reproductive success.

One particular advantage of MONEE is that when two concurrent tasks must be addressed, it is possible to tune selection pressure on-the-fly to effectively balance between the two tasks, favouring the least sought task. This market mechanism is reminiscent of fitness sharing in the sense that it also reappraises fitness, favouring tasks that are less commonly tackled by robots in the population, even though robots' behaviours are under scrutiny, rather than their genetic make-up. Figure 1 illustrates such a setup, where robots have to collect two types of pucks.

Combining environment-driven adaptation and objective-driven optimisation

In this puck-gathering scenario, there are two obvious determinants of selection pressure, i.e., two factors that determine the likelihood of a robot producing offspring. One is distance travelled. This is not an explicit objective, but it is implied by the fact that robots must come within communication range of eggs: robots that move about a lot have higher chances of meeting eggs and therefore procreate at a higher rate than robots that move little. The second factor is the task performance that we explicitly introduced: when reviving, an egg selects a parent (using binary tournament) for the new controller based on the number of pucks collected. For a qualitative view of the importance of these two

selective forces, consider Fig. 2. It plots the combined individuals of 64 runs in four 5,000 clock-tick intervals. Each individual is indicated by a small circle, of which the colour indicates the number of offspring for that individual. The position of the circle shows the number of pucks that individual collected (horizontal axis) and the total distance covered (vertical axis, in pixels in the simulated environment) during its lifetime. For full details of the experimental setup, see Haasdijk et al. (2014).

Initially (left-most panel), there is little variation in terms of pucks collected (the dots are concentrated between 0 and 5 pucks collected). Individuals with high offspring counts are found across the range of distance travelled with a slight concentration between 500-1,000. This indicates that there is little pressure towards movement or collecting pucks at this point. As evolution progresses, at t = 150,000, having offspring becomes contingent on travelling greater distances and collecting pucks; most robots travel substantial distances between 3,000 and 4,000 pixels. At t = 900,000, almost no individuals with more than one child that have travelled less than 2500 pixels. The two right-hand panels show that the number of collected pucks becomes increasingly important. These results indicate that robot behaviour initially adapts to the environment, evidenced by the initial differentiation in distance travelled. As evolution progresses and almost all robots travel substantial distances, the number of pucks collected becomes the dominant factor in determining the chances of producing offspring.

Abstract

The theory of cognitive development from Jean Piaget (1923) is a constructivist perspective of learning that has substantially influenced cognitive science domain. Indeed it seems that constructivism is a possible trail in order to overcome the limitations of classical techniques stemming from cognitivism or connectionism and create autonomous agents, fitted with strong adaptation ability within their environment, modelled on biological organisms. Potential applications concern intelligent agents in interaction with a complex environment, with objectives that cannot be predefined. There are numerous interesting works in developmental robotics going in this direction. In this work we investigate the application of these principles to a close domain: Ambient intelligence, which is extremely challenging but which also presents interesting aspects to exploit, like the participation of human users. From the perspective of a constructivist theory, the learning agent has to build a representation of the world that relies on the learning of sensori-motor patterns starting from its own experience only. This step is difficult to set up for systems evolving in continuous environments, using raw data from sensors without a priori modelling, primarily because they face a bootstrap problem. In this paper we address this particular issue and propose a decentralized approach based on a multi-agent framework, where the system's representations are constructed through a self-organization process that handles the dynamics between experience discretization and learning.

Introduction

Embodiment is a paradigm in cognitive science and AI considering that *cognition* arises from the *interaction* between an *agent* and its *environment*. Contrary to computational theory of mind, an agent has to be embodied and situated, and does not have a predefined *representation*. On the other hand an agent (for example a robot) must be able to construct its own representation of the regularities through its interaction with the environment, whatever its body's capacities and the environment where it is situated. More generally, embodiment is embraced by constructivist theory of cognition, as explained by Ziemke (2001). Constructivism in cognitive science is bound to constructivist epistemology. Particularly Riegler (2001) explains why the *radical con*-

structivism proposed by Von Glasersfeld (1984) is necessary to go further in the understanding of cognition mechanisms. There is a growing interest in AI for constructivist theories, for example such as *Enaction* (Varela et al. (1991)) stemming from the biology field, or constructivist theory of learning (Piaget (1954)) coming from the psychology field. While it is true that constructivist approaches of learning in AI are usually still theoretical, there are also more practical domains that take inspiration from these concepts such as developmental robotics. This article addresses some fundamental issues related to the application of constructivist learning methods to continuous environments. In the following, we will first introduce constructivist methods for artificial learning and the issues related to real application such as in an ambient intelligent system. In this article we focus on the problem of bootstrapping the learning of sensori-motor regularities starting from raw signals, which is a first step in the more general model of a constructivist learning. Then we will present our approach to this problem, based on a decentralized approach using a self-organizing multi-agents system, and provide some preliminary results.

Research issues and related works

Before going any further, let us consider an illustrative example of the addressed research problem. Unknown sensors $\{s_1; s_2...s_n\}$ and actuators $\{a_1; a_2...a_n\}$ are connected to an ambient intelligent system S. S is considered as an autonomous agent that must be able to learn the effects of, for instance, a_x on s_y and s_z . If S receives an objective from the user that involves one of these perceptions/actions, it should be able to take the knowledge of those interactions into account. For example, let us say that a_x is a wireless actionable plug with an unknown device D connected on it. If D is an electric heating, S should become aware that it can affect both temperature (s_y) and energy consumption (s_z) by switching a_x , whereas it can affect luminosity and energy consumption if D is a lamp. These are simple regularities that may seem trivial to learn. This is true if the system's designer defines an a priori representation, for example the definition of events and of how to manage time relations. By doing so, a learning agent may directly focus on what is relevant, and find attended regularities out of a reduced search space. Here we consider the case where the agent has no a priori representation and must both discover how to grasp raw signals and how to learn from them at the same time.

Continuous environment and the discretization process

In real world environments, if we want to avoid an a priori definition of a model, the system has to deal with the complexity of raw data coming continuously from sensors. The perceptual aliasing problem is one of the main issues: the learning agent has to learn precisely what are the boundaries of events both in time and space. But the task of separating an event out of the thread of experience is quite difficult. A human brain seems to be able to focus on the relevant details of experience in order to identify a situation and ignore anything else. In classical AI, particularly with logic based symbolic representation, the exhaustive characterization of a situation is impossible in large environments (Frame Problem), most importantly when considering a large buffer memory of past events. More generally, the question of dealing with the complexity of the real world without using a model or symbolic representation is also known as the Moravec's paradox. This paradox emphasizes the fact that basic sensorimotor skills of living organisms are more difficult to reproduce artificially than high level cognitive abilities, as argued by Brooks (1991). Handling continuous experience is a particularly significant issue for constructivist learning methods, related to their application to real world problems.

Developmental robotics

The field of developmental robotics proposes interesting works in accordance with the constructivist principles presented above and is confronted with the problem of handling continuous environments (see Lungarella et al. (2003) for a review). This research field stems from the assessment that biological organisms go through a period of development before reaching their final form. One of the main ideas is that learning must be facilitated by the progressive increase of the complexity of the environment perceived by the agent while progressively acquiring highly tuned skills. Indeed, at the beginning of his growth, an infant has limited sensor and motor abilities, as well as limitation in his nervous system. At first sight this may be considered as a defect, but we can also consider that it is an advantage regarding the learning process, since it enables to decrease or prevent any data overload, that would not be useful for the first development steps. If the agent is precociously facing a huge quantity of information, learning can be intractable. Thus the management of the development of an artificial agent during the learning process could be an improvement. In developmental robotics, the programmer does not specify a

targeted task; the robot must freely explore its environment by interaction. For example, an *intrinsic motivation* could be expressed in the robot by a certain curiosity which leads it to focus on interesting things, like situations which are neither too predictable nor not enough, as proposed for example by Oudeyer et al. (2007). The capacity of making predictions is a part of the mechanism of development, from which the cognition is built. Cognitive functions of higher level, such as planning, may be seen as a prediction of series of events based on experience. Thus, in continuous environments the definition of the notion of event is crucial. Without pre-given representation, the agent has to learn what an event is, and at the same time it uses events to learn patterns. Before presenting a possible application of such a developmental approach to an ambient intelligent system, it is worth introducing more precisely the constructivist learning paradigm in AI and works related to the problem of bootstrapping regularities from raw experience.

Constructivist learning

In psychology the constructivist theory especially developed by Piaget (1954) postulates that a learning agent constructs its own representation of its world, which it uses to give a meaning to its experience (assimilation). Learning, therefore, is simply the process of adjusting its mental models to fit in new experiences (accommodation). Following Drescher (1991) who takes inspiration from the work of Piaget to propose a model of constructivist learning, many researchers work on the schema learning technique. In this model the pattern of interaction used to build the representation of the agent is called a schema. It consists mainly in three elements: a context, an action and a result. The meaning of a schema is: if the agent executes the action A in the context C, it predicts the result R. Schemas are learned incrementally while the agent performs random actions, in the manner of an infant fumbling. A schema is an interesting structure for a representation since it relates an action to its consequences in an environment, based on agents experience. The learning is not goal-oriented, contrary to classical reinforcement learning for example, where the agent learns which action to execute in which context, depending on the purpose of an external learning task. Here, the agent predicts the consequences of its action, and this knowledge may be used for different purposes. The learning model of Drescher (1991) is very interesting because it offers to agents the possibility to learn abstract concepts grounded in experience thanks to the creation of synthetic items (see Perroto et al. (2010)). However, this model operates on a discrete environment and is quite resource consuming, so that it cannot be applied directly to continuous environments. Also many other research in constructivist learning methods in AI provide valuable results but are often designed for simplified simulated environments (see Guerin (2011) for a survey).

Related works

There are works that propose solutions to overcome the problem of handling continuous environments. For example we can mention Chaput et al. (2003) who advises to use a hierarchy of self-organizing maps (SOM) to improve the schema mechanism of Drescher. In their experiment the environment is represented by binary vectors and the time is managed in a step-based manner, but they argue that this improvement may enable constructivist learning for realistic environments. Further work of Provost et al. (2006) steps in this direction with a system that couples a SOM based discretization process of environment with reinforcement learning for a robot navigation problem.

Linaker and Jacobsson (2001) propose a system that features an event extraction mechanism (classification system) which converts raw multi-dimensional and time-step based sensor data into series of events of a larger time scale. This discretization of raw data into events enables to learn a policy of action on a higher level with a reinforcement learning mechanism. It is clear that the low level event extraction mechanism will drastically influence the other parts of the learning system. The major problem for such an approach lies in the fact that the classification process is unique and defined a priori. Yet, the possible classes generated by the discretization mechanism may differ according to the different patterns in which the variables are involved. A solution to this problem is to let the discretization process evolve, guided by a feedback from the higher levels of learning, so that the classes are always adapted to the learned pattern.

This is exactly the case in the model of Mugan and Kuipers (2007) who propose an event extraction mechanism coupled with a learning system of predictive rules. Events are extracted from the continuous experience as transitions between states that are not predefined. Then predictive rules are learned in order to associate an event to an other. An interesting aspect of this system comes from the feedback provided by the learning system to the event extraction mechanism that enables to create new states, and thus learn refined correlations. Thus, the agent learns to perceive in a way that enables to learn more efficiently. This work enhances the developmental process that interconnects the discretization of experience with learning. However, each aspects of this process (the discretization algorithm, the predictive rules,...) are particular implementations that suit with the specific problem considered. In the following of this paper, our purpose is to make explicit the fundamental components of such a process, and propose a generic model that allows multiple implementations of each aspect, motivated by handling heterogeneous unknown environments.

Model presentation

Learning following a constructivist approach is a promising trail in order to build autonomous agents strongly adapted to their environment. In particular, since there is no assumption

about the representation and the objectives of the system, it suits well the problem where both the agent's sensori-motor abilities and its objectives are initially unspecified. Ambient intelligent systems for example present these characteristics. Like robots, they are considered as autonomous systems composed of sensors and actuators. Particularly for AmI systems, constructivist learning is a possible solution to face the fact that sensori-motor abilities are unknown and evolve over time (a user may add, move or remove sensors and actuators at anytime). Moreover, the large variety of equiment results in countless combinations that make harder the design of an expert representation. In the previous part we mentioned the difficulty to handle continuous environments for constructivist learning methods, in this section we propose a solution to deal with this problem, with the example of an ambient intelligent system.

Description of the problem

Developmental learning relies on agent-environment interactions, that is to say on signals exchanged at the frontier between the agent and its environment. In this model this frontier is represented by a set of numeric continuous variables which represents sensors and actuators $V = \{v_1; v_2; ...; v_n\}$. As illustrated on Figure 1 (a), these variables evolve in time according to their respective allowed values. Let us denote $v_i(t)$ the value of v_i at time t. This continuous flow of signals is interpreted by the agent as an event sequence. In the following we call $experience\ E = \{e_1; e_2; ...; e_n\}$ the set of events constructed by the agent. We assume that there are some regularities in this experience. A regularity can be represented as a pattern that the agent is able to isolate within its experiential space and identify thanks to its recurring nature.

From the point of view of the learning system, there is no difference between variables connected to actuators and variables connected to sensors. So the patterns learned by the system might indifferently involve actions and perceptions. However, it is clear that some actions have to be performed in order to appear in some patterns. Contrary to robotics, the domain of ambient intelligence does not really allow us to let the agent randomly explore its possible interactions with its environment in the first place. A motor babbling behavior (see Mugan and Kuipers (2007)) might be lengthy and its consequences would definitely constitute a nuisance for users, for obvious reasons. Hopefully, an ambient intelligence system presents an interesting property that we can exploit to face this problem: a user is able to directly perform actions. For safety and ethical reasons, a user must always keep control of its environment. So as a design constraint, we consider that for every action that can automatically be performed by the agent, a user should have the possibility to directly perform it. We make the hypothesis that the agent is always able to perceive such an action performed by a user, as a kind of *proprioception*¹, so that if this action

¹the sense of internally perceiving our own movements

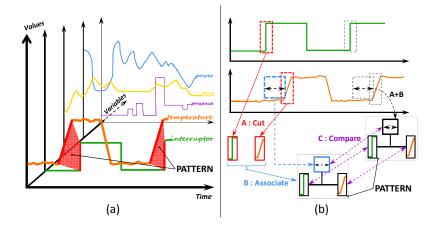

Figure 1: (a) The continuous experience of the system expressed as a set of variables.
(b) The 3 types of operations that enable the construction of patterns. A: Find a temporal reference in order to perceive a variation. B: Find associations between variations. C: In order to reinforce existing structures, modify them or create new ones, it is necessary to be able to compare elements of representation.

becomes involved in a pattern, the agent would be able to perform it by itself later. Najjar and Reignier (2013) refer to this as an *observed action*. Thus the initial random motor babbling is replaced by actions driven by the user, which get involved at the very beginning of the learning process as a form of *motivation* for the developing agent.

Constructing patterns and the bootstrapping problem

A pattern is relevant if it contributes to the creation of new patterns, so that to enable the construction of a representation which justifies them. In other words, the agent has to learn how to perceive efficiently in order to be able to learn more. This circular definition raises a bootstrapping problem similar to the one mentioned by Drescher (1991): finding a context to characterize the association between an action and a result requires to know formerly this association, but learning this association is difficult without knowing the context. This kind of *teleological* issue is typical of the study of living systems.

The purpose of the elementary structure of representation is to express the primary kind of regularity that the agent is able to learn in the first place. For example *schemas* (Drescher (1991)) express a logical and temporal relation between three elements. The *result* is likely to be experienced after the *action* if the *context* was experienced initially. But starting with a set of continuous variables as experience, this raises many questions. What are precisely a context, an action and a result? What are the duration of these elements and their relationships? It seems that these notions are already relative to a form of representation. Of course this issue is avoided if there is an a priori abstraction performed by the designer of the system in order to discretize the environment and guide the learning process.

On the other hand one may consider that the schema or any similar kind of structure like the *functional circle* from Von Uexküll (1992), constitutes an undividable elementary structure that is intrinsic to the agent. Thus, Georgeon and Aha (2013) define the *sensori-motor interaction* as such a primitive. This is reminiscent of the *subsumption architecture* from Brooks (1991), but such methods require to formerly implement such functional circles, and thus to know precisely the agent and its environment. Moreover, this preliminary hardcoding of elementary behaviors may be laborious in complex fields such as ambient intelligence systems.

Apart from specifying arbitrary initial actions and perceptions, one way to solve this problem is to consider a developmental approach. At the beginning of the learning process the agent is fitted with rough sensori-motor abilities which enable it to learn primary patterns, then its abilities develop and the learning of a more accurate representation becomes possible. At one point, the already learned representation can guide the development of the abilities. In biological organisms this task is most probably realized both during phylogenesis and ontogenesis, but it needs to be expressed as a single problem for artificial systems. The "bootstrap learning" as presented in Kuipers et al. (2006) corresponds to this critical problem of getting primary patterns from raw data of uninterpreted sensors (see also Guerin (2011) for a review).

In our model, the elementary structure of representation is composed of two generic notions of *events*. First, a *perception* event is a selected moment in the evolution of a variable, for example a variation or a stable state. Second, an *association* event describes a relation between two events, for example a duration between the occurrences of two perceptions. So it is possible to express a *schema-like* regularity with a combination of association and perception events.

More generally, events involved in associations may be associations, therefore enabling the construction of more complex patterns.

A multi-agent system for the construction of patterns

Our proposal is based on a self-organizing multi-agent system (MAS), where three populations of agents² will interact with each other, guided by a feedback from the global system activity in order to construct relevant patterns and provide a grounded representation. The multi-agent architecture suits naturally the view considering the construction of representation as a self-organization process, as well as the heterogeneity of the domain, and the necessity for the system to be resilient. In the MAS, agents perform a function corresponding to their role in the system, that they can change to explore the possibilities to construct a representation. Rather than specifying an a priori model of perception, or using an exhaustive search, this model relies on the elaboration of collaboration, reinforcement, and internal dynamics within the system. Related to the generic notions of perception and association, we identify three primary functions that are necessary to bootstrap the learning of elementary patterns from the continuous experience as illustrated in Figure 1 (b).

• The first operation "cut" corresponds to the creation of a perception event. The set of possible cut functions is $F^c = \{f_1^c; f_2^c; ...; f_n^c\}$. A cut function that transforms values into events is defined as

$$f_i^c: v_i \to \{e_1^c; e_2^c; ...; e_n^c\}$$
$$V \to E^c$$

with E^c the set of perception events.

In the multi-agent system, *cut* functions are implemented by *Perception agents* which are connected to a continuous variable. These agents create events that represent a particular time period of the evolution of the variable. For example, a *Temporal Window Agent* may produce perceptions based on sliding windows of a given duration. In this case a parameter that conditions the behavior of the agent could be the duration of the window. If the parameter evolves due to feedback received by the agent, it corresponds to the exploration of a new *cut* function.

• The second function type, *compare* functions $(F^s = \{f_1^s; f_2^s; ...; f_n^s\})$ which serve to evaluate the similarity between two events, is necessary to classify and manipulate

events. A *similarity* function compares events to determine if they are similar, and is defined as

$$f_i^s: e_x, e_y \to s$$

 $E \to [0, 1]$

where e_x, e_y are created by the same function (s=1 means totally similar, s=0 totally different).

On Figure 2 we present an example of the activity between a *Perception agent* and a *Similarity agent*. A threshold is defined for s in order to decide the similarity and enable classification (e.g. 0.9). For example, the *temporal window agent* creates an event ec1 which contains the variations compared to the average value of the sliding window. Later another event ec2 is created by this agent and may be considered as similar or different depending on the behavior of the similarity agent involved. If the similarity agent implements a general function f_1^s (intervals of size 3), the two events look similar (3 occurrences in each interval), whereas if it implements a more specific function f_3^s (intervals of size 1) the events are perceived as different.

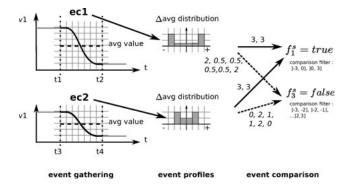

Figure 2: Interaction between a perception agent and a similarity agent.

• Finally the last functions are associate functions $(F^a = \{f_1^a; f_2^a; ...; f_n^a\})$ leading to the creation of association events. An association function that creates an event from two other events is defined as

$$f_i^a: e_x, e_y \to e_z^a$$

 $E \to E^a$

 $(E = E^c \cup E^a)$. For example a *Binary Duration Agent* is defined for two *source events* e_1 and e_2 , and creates an association event for every occurrence of e_1 , characterized by the duration with the previous occurrence of e_2 .

A *Similarity Agent* is associated with a perception or an association agent, in order to classify events created by these agents. For instance, on Figure 3, events are created from

²In the following we will refer to the above-mentioned autonomous learning agent as "the system" in order to avoid any ambiguity with the MAS's agents.

the activity of variables v_1 and v_2 by agents which implement functions f_1^c and $f_{1'}^c$. Different occurrences of e_1^c and $e_{1'}^c$ (source events) are classified by similarity agents. An association agent creates an event e_1^a based on the occurrences of events e_1^c and $e_{1'}^c$, and then creates another event e_2^a later when new occurrences e_2^c and $e_{2'}^c$, are perceived as similar to e_1^c and $e_{1'}^c$. Another similarity agent implementing a function f_2^s compares the association events generated by the association agent f_1^a in order to classify them (as presented on Figure 5).

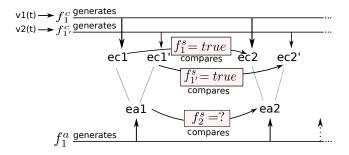

Figure 3: Interactions between the three types of agent.

The evaluation of representation and feedback process

The search space of the system is the set of possible functions $F = F^C \cup C^A \cup F^S$. The relevance of a function can be evaluated according to its participation to the construction of patterns, which is necessarily performed in collaboration with other functions' types. We can represent this feedback by a fitness function $Q: f \in F \to [0,1]$ that defines a function's quality. Then the goal of the system is to find a combination of functions that enables to construct relevant patterns. In other words select the optimal set of functions that maximize the overall quality evaluation. This can be defined as $F' \subset F = \{f' \in F' | Q(f') > T_Q\}$ where T_Q is a threshold for the fitness function.

As illustrated on Figure 4, the mechanism is a circular process initiated by the creation of representation elements from the experience discretized by the *cut* operations. Each time a new element is created, it is compared with previously created elements coming from the same source, and it is fused with a similar existing element or constitutes a new distinction, to form classes of events. Then events are used to create new events with the associate operations, which in turn are compared and so on. These generic functions and the associated structures enable to model a basis for the mechanism of extracting sensori-motor patterns, but there are many ways to instantiate each of them. A given version of a function may suit well the learning of a specific aspect of the system's experience at a certain level, and fail to describe another one. So in this model these different possibilities are processed in parallel, and the best ones are reinforced because they enable the construction of a stable representation. Each instance of a function (an agent) has to evaluate if it contributes to a viable representation or not.

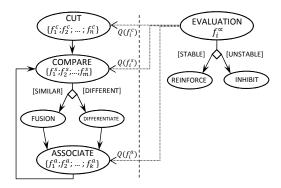

Figure 4: Process of bootstrapping pattern construction according to three types of functions.

The evaluation of patterns may correspond to their ability to make reliable predictions, as used by Mugan and Kuipers (2007). Indeed the adequacy of the representation is tied to the notion of prediction as stated by Von Glasersfeld (1984):

"Quite generally, our knowledge is useful, relevant, viable, or however we want to call the positive end of the scale of evaluation, if it stands up to experience and enables us to make predictions and to bring about or avoid, as the case may be, certain phenomena (i.e., appearances, events, experiences). If knowledge does not serve that purpose, it becomes questionable, unreliable, useless, and is eventually devaluated as superstition."

But in the case of the bootstrapping problem, it is not possible to evaluate the prediction abilities of patterns until we have patterns to consider as a predictive structure. Thus, we introduce a transitional evaluation of *interest*, in order to drive agents to promising areas of the search space and use predictions as a more important feedback in a second step. The interest of primary events is defined according to the notions of specificity and stability. If functions are much too accurate, the classes of events are likely to multiply without being reinforced, and will not constitute regularities. On the contrary, if the operations are much too general, the representation might be quite stable but also unexpressive. Therefore, in order to give feedback to agents, the representation must be evaluated in terms of a tradeoff between accuracy and stability. This intuitive idea is used in order to overcome the bootstrapping problem. Indeed, it enables to guide the activity of the initial rough functions, before first patterns are formed. The specificity of an event can be expressed in relation with a reference event, which corresponds to the more general class, that is to say all occurences of the event. For example for a Binary duration agent, the reference is a set of durations between random events. The *specificity* of an event is: $s(e) = 1 - f^s(e, ref)$ defined between 0 and 1. Let us note |e| the number of occurences of the event $e \in E^{\alpha}$, and E^{α} is the set of event classes generated by the similarity agent among all occurences. The *weight* of an event is defined according to the repartition of the occurences of this event in relation with the other specific events:

$$w(e) = \frac{|e|}{\sum\limits_{s(e_i) > \epsilon; e_i \in E^{\alpha}} |e_i|}$$

The interest of an event is i(e) = min(s(e), w(e)). As illustrated on Figure 5, an association event which has both a high specificity value and weight value, may represent a regularity of the duration between two events, and give a positive feedback to agents that construct these events.

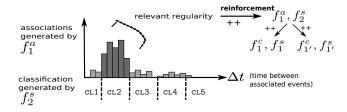

Figure 5: Feedback from an association to participating agents.

The purpose of this architecture is to investigate the dynamics of bootstrapping regularities from continuous signals as a developmental process, without committing to a specific implementation. This is the first step in a more general model of constructivist learning. We let the opportunity to incorporate a variety of agents at different levels into the system for each of the operations involved, in line with the ideas developed by Minsky (1991). In the last section we present preliminary results focusing on the bootstrapping step with a system composed of very simple agents in order to experiment the global mechanism.

Results and conclusion

The experimental setup consists of a simple set of three interacting numeric variables V_1 ; V_2 ; V_3 . V_1 is an interruptor that actions V_2 and V_3 , which vary at different paces and scales. Activations of V_1 are repeated randomly between 2 and 6 seconds after the end of the series of effects on other variables, as represented on Figure 6. The purpose is to verify that structures generated by the system can stabilize on relevant associations, which can enable to bootstrap the pattern learning.

In this experiment, the system is initially composed of a minimal number of elementary agents: one perception agent per variable (a temporal window agent mentioned above which collects variations in a sliding window), and one similarity agent. Each event is represented by a vector (histogram), storing the distribution of the collected values.

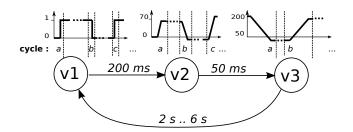

Figure 6: Experimental setup.

Thus the similarity agent compares the intersection percentage between two vectors. At the beginning there is no association agent, since there is no event to connect with. Events that go beyond a certain threshold of interest lead to the creation of an association agent, but only if the pair of agents (perception agent & similarity agent) is stable. A mesure of stability takes into account the changes of important criteria for the pair, such as the number of event classes and the respective interest of each events. Stable pairs that do not include any interesting event arouse a negative feedback on their agents, and lead to the creation of new agents for exploration and encourage agents to use other functions.

So when an association agent is connected to two events that match with a regularity, it must appear as an interesting event. For example Figure 7 shows the first interesting association event that is found (after 34 activations of V1). This association forms a three-events pattern which corresponds to the regularity involving the variation of V1 followed by the variation of V2.

As expected this kind of rough pattern can enable to bootstrap a more elaborated learning mechanism since it contains necessary information about the events and their relation in time to construct a predictive structure. In a second step, there can be a feedback from the prediction mechanism to the discretization process, so that event perception learning is oriented according to its utility for predictions. Further work will be mainly dedicated to the implementation of this mechanism, but also includes: investigate the application of this generic process to higher level in the representation; and also study the possible internal dynamics within the population of agents that can be exploited to improve the performance of the system, and develop self-organization process. In this article, we point out the fundamental problem of bootstrapping learning of sensori-motor patterns from continuous environments in a constructivist perspective of learning. We propose to tackle this problem with an unconventional decentralized approach. The multi-agent architecture is used to model the self-organization process of the construction of representation and the dynamic between learning and the discretization of experience. This model is still in an early stage of development but presents interesting theoric and applicative perspectives. We show that the proposed

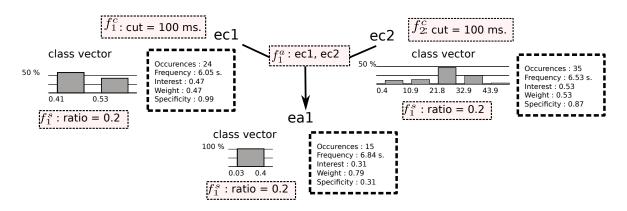

Figure 7: Example of a pattern.

mechanisms lead to the recognition of significative events and regularities without any a priori knowledge. Despite its apparent simplicity, the problem we address is complex if not avoided thanks to an abstraction effort in the design of a preliminary representation. These results are very encouraging and reveal a great potential for such an approach. Going deeper in the understanding of such mechanisms will allow to efficiently address many problems. Applicative fields such as Ambient Intelligence features both learning issues related to the undeterminism of the system, and the practical constraint to handle continuous environments.

Habit-based Regulation of Essential Variables

Matthew Egbert¹ and Lola Cañamero¹

¹ Embodied Emotion, Cognition and (Inter-)Action Lab, University of Hertfordshire, School of Computer Science, Hatfield, UK, AL10 9AB mde@matthewegbert.com

Abstract

A variety of models have been developed to investigate "homeostatic adaptation," a mechanism inspired by Ashby's homeostat, where a plastic control medium is reorganized until one or more essential variables are maintained within predefined limits. In these models, "habits" emerge, defined as behavior-generating mechanisms that rely upon their own influence to maintain the conditions necessary for their own persistence. In this paper, we present a recently developed sensorimotor-habit-based controller that is coupled to a simulated two-wheeled robot with a simulated metabolism. The simulation is used to demonstrate how habits can have the same essential variable(s) as the metabolic or "biological" organism that is performing the behavior, and that in certain conditions when this is the case, the emergent habits will tend to stabilize essential variables within viability limits. The model also demonstrates that an explicit pre-specification of (A) which variables should induce plasticity and (B) which values of those variables should induce plasticity is not always necessary for homeostatic adaptation of behavior.

Introduction

Over the past few decades, a range of "embodied" approaches to the study of the mind have emerged, including: enaction (Stewart et al., 2010), dynamical approaches to cognition (Beer, 1997), the sensorimotor approach to perception (O'Regan and Noë, 2001), and embodied AI/Robotics (Brooks, 1990; Pfeifer and Bongard, 2006). Unifying these approaches is the notion that instead of investigating abstract computational problems such as chess, research in robotics and AI should instead focus upon embodied, embedded agents that use ongoing interactions with their environment to accomplish "intelligent behavior," where intelligence is evaluated by its contribution to the survival of the agent, (see e.g. Steels, 1995). But, the notion of system survival or "viability" in the context of robotics can be more challenging than it first appears. Biological organisms are far-from-equilibrium, dissipative structures that depend upon ongoing processes of self-production and selfmaintenance to counteract their tendency to degrade (Kauffman, 2000; Nicolis and Prigogine, 1977; Schrödinger, 1944; Maturana and Varela, 1980), but conventional robots do not share this property and thus there can be challenges in relating the behavior of artifacts to the behavior of biological organisms. This difficulty has led to different emphasis placed upon the metabolic organization within the embodiment community, with some proponents more or less ignoring the concept and others arguing that the metabolic organization is fundamental (Froese and Ziemke, 2009). As an example of the former, metabolism is seen as largely irrelevant to the sensorimotor approach to perception, with suggestions that a missile guidance system could have some minimal perceptions (O'Regan and Noë, 2001, p. 82) and that a machine, if sufficiently complex, could be considered aware (with no mention of metabolism / self-production). In contrast, many studies in embodied- and evolutionary-robotics acknowledge the metabolic-organization and its role of defining viability limits as important and set out to investigate how regulation can be accomplished that maintains viability. Most of these, however, do not model in detail the processes through which the viability-limits are defined (e.g. metabolism), as the focus is instead upon how a particular form of regulation can be accomplished (e.g. Avila-Garcia and Cañamero, 2004; Beer, 1995), but some of our recent models include in detail both behavioral dynamics and the metabolic dynamics that define the viability limits. Using these models, we have demonstrated how organisms can respond to the processes that define their viability limits to perform an ongoing, in-the-moment evaluation of the environment (Egbert et al., 2009), that allows an organism to behave in a history-dependent and adaptive way that integrates multiple environmental and internal factors into an adaptive behavior (Egbert et al., 2010b; Egbert, 2013) that may play an interesting role of facilitating adaptive evolution (Egbert et al., 2010a).

Some "enactivists" (Stewart et al., 2010) believe that the metabolic-organization fundamentally underlies mind. In particular, it has been argued that the metabolic-organization underlies a modern concept of intrinsic teleology, in which an organism's survival grounds teleological (Weber and Varela, 2002) and normative (Barandiaran and Egbert, 2013) descriptions of its behavior. In this view, organisms act to

satisfy the needs that are the result of their own precarious, metabolic organization (Weber and Varela, 2002). But of course, not all behavior, adaptive or otherwise, is a direct response to biological needs and dynamics; not all behavior occurs to maintain biological essential variables within viability limits, and so what can biological embodiment contribute, to "higher" forms of adaptive behavior, i. e. beyond the metabolism-based chemotaxis of bacteria? One proposal stems from the observation that aspects of perception, learning and sensorimotor behavior appear to have properties in common with self-maintaining organisms. In particular, an analogy is drawn between habits seen as self-maintaining patterns of behavior, and biological organisms seen as selfmaintaining metabolic entities (Di Paolo, 2003; Barandiaran, 2007, 2008). By viewing habits as having the same precarious, self-maintaining organization as biological entities, it becomes possible to understand how, in a way similar to the grounding of many survival-based behaviors in metabolism, other behaviors can be grounded in the needs of habits themselves. In metabolism-based chemotaxis, bacteria act to maintain their biological essential variables within limits and analogously, habit-based behavior maintains the conditions necessary for the persistence of the habit itself, i.e. the persistence of the behaviour and the mechanism(s) that generate it. Put another way, biological embodiment grounds survival, the "mother of all values" (Weber and Varela, 2002; Di Paolo, 2003), and habits are autonomous "mental life forms," that ground the others (Di Paolo, 2003; Barandiaran, 2007, 2008).

In a set of minimalistic computational models, Di Paolo (2000, 2003) demonstrated how a behavior-generating mechanism can stabilize the conditions necessary for its own persistence. The first model involved a simple simulated two-wheel, two-light-sensor robot, controlled by a plastic continuous time recurrent neural network. In a design inspired by Ashby's homeostat (Ashby, 1952), the weights of the connections in the neural network were fixed when the neural firing-rate was within a predefined region, but outside of this region the weights changed according to deterministic plasticity rules. A genetic algorithm succeeded at identifying model parameters (initial weights, which plasticity rules applied to which synapses, etc.), that resulted in networks that both avoid plasticity and perform phototaxis, and we can say that the neural network configurations that emerged in this model were self-maintaining behaviorgenerating mechanisms. Why? A configuration of weights in the neural network is precarious in the sense that it can only persist if plasticity is avoided and it has viability-limits in that neuron firing rates must not leave predefined bounds if the behavior-generating mechanism is to persist. The firing rates of the neurons are influenced by internal neuron activity, but also by the sensorimotor dynamics of the behavior: the neurons influence the motors which influence how the environment influences the sensors, which, coming

full circle, influence the neurons. The stability of a particular configuration of weights of the NN therefore depends, in part, upon the behavior that it drives, and thus can be considered to be a self-maintaining behavior-generating mechanism.

In this first model of Di Paolo's, there is no modeled metabolism, biological essential variables or biological viability limits. The behavior is phototaxis because of selection pressures applied during the artificial evolution. We could imagine that the agent has a biological (i. e. metabolic) need to move toward the light, but even so, the coupling of this need and the self-maintaining behavioral mechanism was accomplished through an evolutionary process. Is there a way that the self-maintaining behavior-generating mechanisms (henceforth "habits") and the self-maintenance of the organism could be more tightly integrated? In order to address this, Di Paolo (2003) developed a second model consisting of a simulated, Braitenberg-inspired robot, with plastic mappings between sensors and motors. These mappings undergo stochastic change when the battery (an analog to metabolism) is outside of certain pre-defined limits. This is a step forward in that the biological needs and the habits are intertwined in a cycle of dependence, where the maintenance of a viable battery level depends upon the habit, but also the stability of the habit depends upon the battery level remaining within bounds, for if the habit drives the metabolism outside of the biological viability limits, the behavior-generating mechanism will also lose viability due to the stochastic weight-change process. In a different approach to coupling behavior to metabolic needs, Iizuka et al. (2013) selected the limits for the induction of plasticity such that when there was no sensor activity, the weights of the network would change. In this way, the system could only become stable when it was performing phototaxis. The relationship between the essential variable (a "photosynthetic metabolism" that justifies phototaxis as a target behavior) and the behavior has been hard-wired by the designer, in the sense that the robot can adapt to inversions of its visual field, but could not adapt to its phototactic-needs becoming photophobic-needs.

For all of the models presented above, the limits of plasticity, i. e. the surface between the states where plasticity does occur and where it does not, are parameters of the model that are pre-specified. It is also the case that for every model, one or more variables are given a special privileged status as a "plasticity inducing variable". In the first model of Di Paolo's presented above, and in Iizuka's model, these are the neuron firing rates. In the second model of Di Paolo's, it is the state of the "biological" essential variable, i.e. the battery state, and it is through this explicit specialization of this variable that the biological dynamics and the mental dynamics are coupled. In this paper, we use a newly developed model of habits, coupled to a simulated two-wheeled robot with simulated metabolic dynam-

ics to demonstrate how it can be possible to couple selfmaintaining behavior-generating mechanisms with biological essential variables without pre-specifying the region of plasticity and moreover, without pre-specifying which variables are plasticity-inducing variables.

In the next section we describe the robot, its simulated metabolism and its habit-based controller. We then describe two scenarios that we use to demonstrate that by including an interoceptive sensitivty to the state of the metabolism as a sensory-variable, self-reinforcing patterns of behavior emerge that stabilize that metabolic dynamics. We present the results of simulations of these scenarios before interpreting and discussing them.

Simulation

Robot and environment. We simulate an simple robotic agent embedded in a two-dimensional square environment 8 units wide, with periodic boundary conditions. The robot has two directional light sensors and two independently driven motorized wheels. The motion of the robot is $\dot{x} =$ $\cos(\alpha)(m_l+m_r); \dot{y}=\sin(\alpha)(m_l+m_r); \dot{\alpha}=2(m_r-m_l),$ where x,y is the robots spatial position, $\alpha \in [-\pi,\pi]$ is the robots orientation and $m_l \in [-1,1]$ and $m_r \in [-1,1]$ are the robots left and right motor speeds. The robot's light sensors are located at $x + r \cdot \cos(\alpha + \beta), y + r \cdot \sin(\alpha + \beta)$, where r=0.25 is the robot's radius and $\beta=\pm\pi/3$ is the angular offset of the sensors from α , the heading of the robot. The activation of each sensor is determined by the equation below, where $b = [\cos(\alpha + \beta), \sin(\alpha + \beta)]$ is a unit vector indicating the direction that the sensor is facing, c is the vector from the sensor to the light (which is located in the center of the arena at (0,0), and D is the distance from the sensor to the light.

$$s = \frac{(\boldsymbol{b} \cdot ||\boldsymbol{c}||)^+}{1 + D^2} \tag{1}$$

Metabolism. We simulate the robot as having a metabolism with intrinsic dynamics that are indirectly influenced by the motor behavior. The simulated metabolism is inspired by the blood-sugar dynamics of a diabetic, where hormonal regulation prevents the blood-sugar from diverging, but is insufficient to prevent blood-glucose levels from leaving healthy limits. The dynamics of diabetes has been simulated since this work is part of the ALIZ-E project, where we are investigating how to help diabetic children learn to manage their disease. Part of this support involves developing a better understanding of how behaviors relate to essential variables such as blood-sugar, as well as to reflexive hormonal modulators such as insulin and glucagon (Lewis and Cañamero, 2014), and how diabetes-related (good and bad) habits form and how they can be changed (from bad to good) in support of self-efficacy.

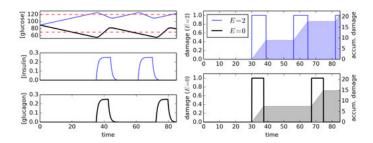

Figure 1: Essential variable dynamics in two worst case scenarios, always feeding (blue) and never feeding (black). Left: Glucose, insulin and glucagon dynamics. Viability limits for the essential variables are indicated by dashed red lines. Right: damage and accumulated damage.

param.	value	description
c	1.0	rate of glucose use / consumption
f_U, f_I	20, 0.1	efficiency of hormonal modulation
b_U,b_I	60.0, 120.0	threshold G-concentrations
c_U, c_I	0.25, 0.25	rate of hormonal production
d_U, d_I	1.0, 1.0	rate of hormone elimination
au	5.0	delay in hormonal response

Table 1: Metabolism-related parameters

The modeled metabolism is not intended to be a realistic simulation of blood-sugar dynamics, but just to qualitatively capture the dynamics of an hormone regulated essential variable that is inadequately regulated, i.e. a variable for which the hormonal regulation is insufficient to keep the system within its viability limits. The model consists of three coupled delayed differential equations, which represent: G, blood-glucose concentration, the essential variable which must remain within limits if the system is to be considered in a healthy state; I, the concentration of insulin, a hormone that removes G from the blood when it is above a threshold, and U, the concentration of glucagon, a hormone that releases G into the blood when it is below a threshold. In these equations, the function $[a < b] \equiv 1$ when a < b, and 0 otherwise.

$$\frac{\mathrm{d}G}{\mathrm{dt}} = E + f_U U - f_I I G - c \tag{2}$$

$$\frac{\mathrm{d}I}{\mathrm{dt}} = [b_I < G_{t-\tau}] c_I - d_I I \tag{3}$$

$$\frac{\mathrm{d}I}{\mathrm{dt}} = [b_I < G_{t-\tau}]c_I - d_I I \tag{3}$$

$$\frac{\mathrm{d}U}{\mathrm{d}t} = [G_{t-\tau} < b_U]c_U - d_U U \tag{4}$$

We defined viability limits such that the system is considered to be healthy if $G \in [b_U, b_I]$. Leaving the viability limits will eventually trigger hormonal regulation of G back into the viability region (with a delay of τ), but the model is configured such that similar to a diabetic, the hormonal regulation is insufficient to maintain G within healthy limits. When the robot is within 2 spatial units of the light it is considered to be "feeding" and the variable E is set to 2, and otherwise E=0. Thus, the behavior of the robot influences G and, as we shall see, if certain patterns of behavior are performed, it is possible for the value of G to remain within the viability limits indefinitely. However, if the robot performs non-ideal behaviors, G will leave the viability limits, and thereby accumulate "damage," defined as the quantity of time when $G \notin [b_U, b_I]$. Figure 1 shows example trajectories for G, I and U for two worst-case behaviors (the robot always eating, and the robot never eating) with the plots on the right indicating the damage and accumulated damage suffered in these scenarios. Throughout this paper, time and time-related values such as τ are specified in arbitrary time-units, where one time-unit is the time in which a robot traveling at full-speed moves 2 spatial units.

Habit-based controller We have recently developed a plastic, self-modifying dynamical system called an Iterant Deformable Sensorimotor Medium (IDSM) (Egbert and Barandiaran, 2014). This system was designed to act as a robot controller that supports the formation of "habits" conceived of as precarious, self-maintaining patterns of sensorimotor behavior. When coupled to a robot's sensors and motors, the IDSM (1) causes the robot to repeat behaviors that it has performed in the past, and (2) allows for the reinforcement of patterns of behavior through repetition, such that the more frequently and recently a pattern of behavior has been performed, the more likely it is to be performed again in the future. If a pattern of behavior is not performed for a period of time, it becomes less likely to be re-enacted, but when behaviors are performed, they become more likely to be repeated in the future, and in this way, self-maintaining patterns of behavior emerge. Metaphorically, the IDSM works similarly to the paths made by animals through the woods or through a field of grass. As sensorimotor trajectories are experienced, pathways are worn in to the IDSM's "sensorimotor-space," such that future sensorimotor pathways are likely to be similar to those pathways that have been taken in the past. In the remainder of this section, we provide an overview of our IDSM architecture. Much of the text here comes from (Egbert and Barandiaran, 2014), which provides a much more detailed description of the IDSM and its dynamics.

The IDSM operates by developing and maintaining a history of sensorimotor (SM) dynamics. This history takes form of many *nodes*, where each node describes the SM-velocity at a SM-state at some point in the past. As the agent behaves, and its SM-state changes, nodes are added, such that a record is constructed of how sensors and motors have changed for various SM-states during the system's history. These are used to determine future motor-actions such that when a familiar SM-state is encountered, the IDSM pro-

Symbol Description

x current SM-state

 N_p SM-state associated with node N (in normalized SM-space coordinates)

 N_v SM-velocity indicated by node N (in normalized SM-space coordinates)

 N_w weight of node N

d(x, y) distance function between two SM-states

 $\omega(N_w)$ function describing how the weight of a node scales its influence

 $\phi(y)$ function describing the "familiarity" (local density of nodes) of SM-state y

Table 2: Glossary of symbols and brief descriptions.

duces behavior that is similar to the behavior that was performed when the agent was in a similar situation in the past.

More formally, each node is a tuple of two vectors and a scalar, $N = \langle \boldsymbol{p}, \boldsymbol{v}, w \rangle$, where \boldsymbol{p} indicates the SM-state associated with the node (referred to as the node's "position" in SM-space), \boldsymbol{v} indicates a velocity of SM-change, and the scalar, w indicates the "weight" of the node, a value that partially determines the overall influence of the node. We shall refer to these components using a subscript notation, where the position, SM-velocity, and weight of node N are written as $N_{\boldsymbol{p}}$ and $N_{\boldsymbol{v}}$ and $N_{\boldsymbol{w}}$, respectively.

As a robot controlled by the IDSM moves through SM-states, new nodes are created recording the SM-velocities experienced at different SM-states. Specifically, when a new node is created, its "position," N_p is set to the current SM-state; its "velocity," N_v is set to the current rate of change in each SM-dimension, and its weight, N_w is set to 0 (an initial value that does not imply that the node is ineffectual, see below). The two vector terms $(N_p$ and N_v) are calculated in a normalized sensorimotor space, where the range of all sensor and motor values are linearly scaled to lie, in each dimension, between 0 and 1.

New nodes are only added when the density of nodes near the current SM-state, as described by the function ϕ , is less than a threshold value, $\phi(\boldsymbol{x}) < k_t = 1$. This density function, ϕ , can be thought of as a measure of how many nodes there are near to the SM-state \boldsymbol{x} , and how heavily weighted those nodes are. Loosely speaking, it is a measure of how "familiar" the SM-state is, and it is calculated by summing a non-linear function of the distance from every node to the current SM-state, $d(N_p, \boldsymbol{x})$, scaled by a sigmoidal function of the node's weight, $\omega(N_w)$, as described in Equations 5–7.

$$\phi(x) = \sum_{N} \omega(N_w) \cdot d(N_p, x)$$
 (5)

$$\omega(N_w) = \frac{2}{1 + \exp(-k_w N_{sv})}; \ k_\omega = 0.025$$
 (6)

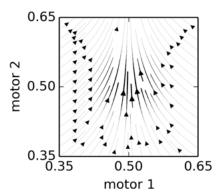

Figure 2: The influence of a single node, with $N_p = (0.5, 0.5)$, $N_v = (0, 0.1)$, and $N_w = 0$. In this didactic scenario, N_v only has a non-zero component in the motor-2 dimension, and thus the node's "velocity" influence causes motor-2 to increase, and its "attraction" influence causes motor-1 to approach a state of 0.5.

$$d(N_{p}, x) = \frac{2}{1 + \exp(k_d ||N_{p} - \boldsymbol{x}||^2)}; \ k_d = 1000 \quad (7)$$

After a node is created, its weight changes according to equation 8, where the first term represents a steady degradation of the node's influence, and the second term represents a strengthening of the node that occurs when the current SM-state is close to the node's position. This latter term allows for the self-reinforcement/self-maintenance of patterns of behavior, such that patterns of behavior that are repeated are more likely to persist than those that are not reinforced.

$$\frac{\mathrm{d}N_w}{\mathrm{d}t} = -1.0 + r(N, \boldsymbol{x}) \tag{8}$$

$$r(N, \boldsymbol{x}) = kd(N_{\boldsymbol{p}}, \boldsymbol{x}) \tag{9}$$

A short period of time after creation (10 simulated time-units), nodes are activated, meaning that they are added to the pool of nodes that influence the motor state. Every activated node influences the motor state, but at any one time only a subset of these will have a substantial influence, for the influence of a node is scaled non-linearly by its distance from the current SM-state by the same distance function used in ϕ above (Equation 7). The influence of each node is also scaled by its weight according to Equation 6, and thus nodes that are close to the current SM-state and nodes with higher weights have a greater influence.

The influence of a node can be broken down into two factors: a "velocity" factor and an "attraction" factor. The velocity factor is simply the motor components of the N_v vector, but the attraction factor, is slightly more complicated. It is a sensorimotor-"force" that draws the system towards the node. This tends to result in a motion in SM-space towards regions of SM-space that are familiar, i.e. for which there is a higher density of nodes and it can compensate for

stochasticity in the environment or perturbations to behavior (see Egbert and Barandiaran, 2014 for details). The attraction vector has its component parallel to N_v removed to prevent it from interfering with the velocity influence of the node (again, see Egbert and Barandiaran, 2014 for details). Figure 2 provides a visualization of the influence of a single node in a hypothetical 2-motor, 0-sensor IDSM. In this example, N_v is exactly vertical, so all horizontal motion is due to the attraction component, and vertical motion is due to the velocity component.

Equations 10-11 describe how the IDSM influences the motor state. The velocity and attraction influences of every node are scaled by the node's weight and distance to the SM-state, and then these are all summed before being scaled by the density of the nodes at the current SM-state such that the influence of all the nodes is averaged and not cumulative. Obviously, the IDSM only has direct control of its motors and the sensor-components of the SM-state are determined by the systems interaction with its environment. Accordingly, the superscripted- μ notation in the equations below indicates where we are only using the motor-components of the indicated vector terms.

$$\frac{\mathrm{d}\boldsymbol{\mu}}{\mathrm{d}t} = \frac{1}{\phi(\boldsymbol{x})} \sum_{N} \omega(N_{\boldsymbol{w}}) \cdot d(N_{\boldsymbol{p}}, \boldsymbol{x}) \cdot (\underbrace{N_{\boldsymbol{v}}}_{\mathrm{Vel.}} + \underbrace{A(N_{\boldsymbol{p}} - \boldsymbol{x}, N_{\boldsymbol{v}})}_{\mathrm{Attraction}})^{\boldsymbol{\mu}}$$

$$A(\boldsymbol{a}, N_{\boldsymbol{v}}) = \boldsymbol{a} - \boldsymbol{a} \cdot \frac{N_{\boldsymbol{v}}}{||N_{\boldsymbol{v}}||}$$

$$(10)$$

Experiment and Control Scenarios We compare two scenarios. In the experimental scenario, the SM-space of the IDSM has two motor dimensions: (the left and right motor of the robot) and three sensory dimensions: its two directional light-sensors, and a direct sensory perception of its essential variable, G (scaled linearly such that the range $G \in [50, 130]$ lies in normalized sensorimotor coordinates in [0,1]). In the control scenario, everything is the same except that the IDSM is not sensitive to G. To keep the total number of SM-dimensions the same in both scenarios, the sensitivity to G was replaced with a motor that has no effect whatsoever. The control is included primarily to show that the task is not trivially solved.

We simulated 25 trials of each scenario. At the start of each trial, we randomly initialized the IDSM with 10000 nodes. These were generated by performing 200 random walks in the 5 dimensional SM-space, each starting from a random location within the SM-space with subsequent loci calculated according to the following equation, $\boldsymbol{l}_{i+1} = \boldsymbol{l}_i + \boldsymbol{r}$, where the components of \boldsymbol{r} are selected from a flat distribution [-0.05, 0.05] and where any components that would take l_i out of the normalized SM-volume are inverted. Nodes were added at each locus of the walk l_i with $N_{\boldsymbol{p}}$ set to l_i , $N_{\boldsymbol{v}}$ set to $l_{i+1} - l_i$, and $N_w = 0$. We then placed

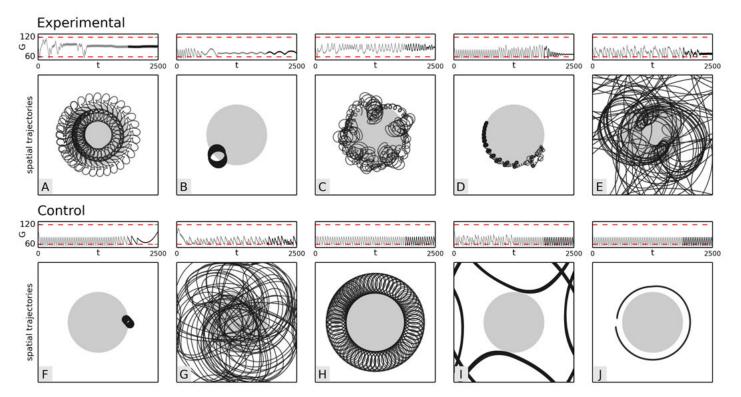

Figure 3: Essential variable and spatial trajectories of the five best performing control and experimental agents. The square plots indicate the spatial trajectories taken by each agent during the final 625 time-units of its simulation (the period during which damage was evaluated). In these plots, the filled-circle indicates the feeding-region. Above each spatial plot, the essential variable, *G* is plotted against time, with the viability-limits indicated by red-dashed lines and the period corresponding to the spatial plot indicated by a darker line.

the robot at a random initial location within the arena, with the essential variable initialized to a value at the center of its viability region (G=90) and the concentration of the regulatory hormones I and U set to 0. We then allowed the IDSM to control the robot and tracked the position of the robot and the trajectories of G,I, and U for 2500 simulated time units, so that we could evaluate the behavior of the robot, and the extent of its success at maintaining the essential variable within viability limits.

Results

To evaluate the performance of each trial, we measured the amount of damage accumulated during the final 625 time-units of each simulation. Figure 3 shows the spatial trajectories and the glucose concentration trajectory plotted against time for the top 5 performing experimental and control trials. We can see that by the end of the simulation, all five of the plotted experimental trials have behavior that maintains G within these limits (although the trajectory in Trial B appears to be on an amplitude-increasing cycle that may eventually leave the viability limits). In comparison, none of the control trials appear to have stabilized G within the viability limits. Three of the experimental agents manage to

avoid incurring any damage during this period, and none of the control agents are as successful. A variety of spatial trajectories can be observed, both in the spatial dynamics and in the dynamics of G. Figure 4 shows the accumulated damage for each trial during this last quarter of the simulation. A Mann-Whitney-Wilcoxon test of these values indicates that the experimental agents are better at maintaining the essential variable within limits to a statistically significant degree (z=-3.13, p<0.002).

Discussion

The IDSM supports the formation of self-maintaining patterns of behavior by (1) assembling a collection of "nodes" that track the SM-state-velocity for different SM-states, (2) using these nodes to drive later behavior, and (3) having these nodes, which perpetually degrade, depend upon a mechanism of self-reinforcement to persist. The self-reinforcement of a node is accomplished by the re-visitation of SM-states near to the node's "position" (N_p) , and so only patterns of behavior that repeatedly visit SM-states can persist. Therefore, in the experimental scenario where the IDSM is sensitive to the essential variable, G, the only patterns of behavior that will persist will be those where values

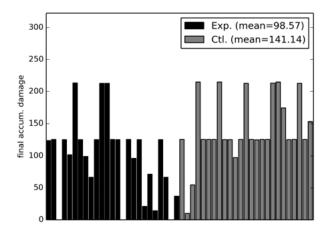

Figure 4: Final accumulated damage for each of 25 experimental and 25 control trials. A higher bar indicates greater damage incurred, i.e. worse performance.

of G are regularly revisited in a way that correlates with the other sensorimotor state variables. In several of the experimental trials, the stable pattern that emerged was one where G was within the viability limits. Why? One possible explanation is that the dynamics of G are more reliable within the viable region than near or outside of it. When G has been inside the viable region for the system's recent history, U=0 and I=0, and thus G changes at a constant rate determined by E. In contrast, when G has recently left the viability limits, one of the hormones will increase in concentration and the way that G changes becomes less correlated with the other sensorimotor variables, (especially given the delay in the differential equations). Thus it seems more likely for the system to find a repeating sensorimotor pattern when it is within the viable region.

For Ashby's homeostat and the robot controllers that it inspired, the stability of the controller has been related to the notion of an $ecological\ invariant$; a relationship with the environment that is maintained by the behavior and that the behavior depends upon. By including the state of G as an interoceptive sensory input, the dynamics of G become part of the habit's sensorimotor "environment" (Buhrmann et al., 2013), such that a behavior must cause G to change in a repetitive way if it is to persist. G is the biological essential variable, but once it is added as a sensory-variable to the IDSM, its dynamics are also essential to the persistence of the habit. The mental and biological autonomous structures are thus intertwined in the sense that they share an essential variable.

Perhaps ecological *invariant* is a bit of a misnomer in this model, as it is not the fixed state of G or any other variable that determines the stability of a pattern of behavior, but more the reliability of a repeated dynamic. In both the control and experimental agents, the behaviors displayed to-

wards the end of the trials are cyclical. This is due largely to the dynamics of the IDSM, where again, only patterns of SM-activity that repeat are reinforced, and as discussed above, only reliable interaction with the environment can result in repeated patterns of SM-activity. At times, the internal dynamics and the environmental interaction are "discordant", in the sense that the motor activity driven by the IDSM does not result in reliable sensory input and the internal dynamics do not "resonate" with the environment in a self-stabilizing manner. As an example of this, consider the more chaotic behavior in Trial E of Figure 3, where the agent is moving around the whole arena, irregularly encountering the feeding area. These irregular sensorimotor trajectories are inherently less stable than those that cause a repeated pattern of sensorimotor state, such as those demonstrated by the subsequent, radially-symmetrical patterns in Trial E, and most of the other agents depicted in Figure 3 (perhaps most apparent in trials A, H, I and J).

In previous attempts to couple biological essential variables to self-maintaining behavior-generating mechanisms, it has been argued that it is necessary to have two nested closed-loops; the first loop being a behavioral coupling between the environment and the organism and the second being an evaluation of the first via an essential variable. such that when the biological essential variable goes out of bounds, the behavior-generating mechanism is reorganized (Di Paolo, 2003). The IDSM-based habits in the experimental scenario are indeed dependent upon the maintenance of a biological essential variable, but we would argue that the two-nested-feedback loop description is not the best way to describe the homeostatic adaptation demonstrated in our model, in that the relationship between the operating limits of the habits and the operating limits of the simulated metabolism are more integrated here than in previous models. The habit does not depend upon the behavior because of a prescribed threshold and response; i. e. it is not due to a random reorganization of the system that is brought about by a pre-specified essential variable going outside of some pre-specified viability limits. Instead, the stability of the behavior and its behavior-generating mechanism is directly dependent upon the repetition of a particular trajectory of the sensorimotor variables, including G. We propose that in this paper we see an example of homeostatic adaptation that blends these two feedback loops into one, suggesting that having two nested feedback loops may not always be necessary.

The system does not always find stability within the viable region, and indeed in several cases (about half) the experimental agents fare no better than the control agents. In these cases, habits have still emerged, but they are unhealthy habits in the sense that they do not maintain the biological essential variable within limits. In ongoing work, and as part of the ALIZ-E project, we are working with our colleagues to develop "diabetic robots" with a simulated

glucose/insulin/glucagon metabolism, that diabetic children can interact with in different ways to investigate how interaction, or modification of the environment could modulate unhealthy habits into healthy habits. By helping the robot transform unhealthy habits into healthy habits, the diabetic children will develop greater self-efficacy, self-confidence and self-esteem, enabling them to better manage their disease (Lewis and Cañamero, 2014). We believe that models such as that presented here can provide insight and fresh perspectives into the relationship between habits and health and how such habits can be better managed.

Conclusion

We have presented our most recent exploration with the IDSM, demonstrating how it can regulate behavior to stabilize essential variables within limits simply by having the state of the essential variable included among its sensors. When a habit emerges in this configuration, it depends upon the dynamics of the biological essential variable, and in this way have demonstrated the possibility of more tightly integrated biological and mental autonomous structures.

Active Shape Discrimination with Physical Reservoir Computers

Chris Johnson¹, Andrew Philippides¹ and Philip Husbands¹

¹Centre for Computational Neuroscience and Robotics University of Sussex cj82@sussex.ac.uk

Abstract

We present the first example of 'minimally cognitive' sensorimotor behaviour arising from a body as physical reservoir. By revisiting an experiment introduced by Beer (1996) and replacing the continuous-time recurrent neural network (CTRNN) therein with networks of mass-spring-dampers we demonstrate that bodies may be exploited for more than control and pattern generation and take over some tasks which were previously thought to require a central nervous system.

Introduction

The importance of embodiment in both generating and understanding adaptive behaviour has been increasingly recognised over recent years (Pfeifer and Bongard, 2007). This has resulted in a renewed focus on the form and function of the body. The exploitation of inherent, often passive, dynamics has demonstrated that there is much to be gained, in terms of efficiency and simplification of control, when body-brain-environment interactions are balanced and harmonious (McGeer, 1990; Iida and Pfeifer, 2004; Shim and Husbands, 2012; Zhao et al., 2013). Pfeifer and Iida (2005) have coined the term morphological computation to refer to the way in which a judiciously selected body morphology can be shown to simplify the task of a controller and might be considered to be 'doing' the computational work it had rendered unnecessary. An interesting, and as yet underexplored, extension of this line of thought is to consider how much explicit and active information processing the body might be capable of, further blurring the line between the nervous system and the body. In fact it has already been shown (Valero-Cuevas et al., 2007) that the tendon network of a human finger performs joint torque mode selection in response to varying ratios of tendon tensions: a biological example of explicit morphological computation in action.

This paper describes research intended as a first step towards exploring the information processing potential of networks of simplified muscle-like units acting within an embodied agent engaged in adaptive behaviour. In this work we follow Hauser et al. (2011, 2012), who have reframed morphological computation in compliant bodies as a branch of

reservoir computing (Maass et al., 2004; Lukoševičius and Jaeger, 2009). Hauser et al. (2011) presented networks of mass-spring-damper elements, and showed that with the addition of a simple linear readout these spring networks can perform complex computation requiring non-linear transformation and integration, such as the approximation of filters and inverse kinematics for robot control. These particular networks are of especial interest because they are physically realisable and because of their similarity to various biomechanical muscle models (Hill, 1938; Seyfarth et al., 2002; Baratta and Solomonow, 1990).

In Hauser et al. (2012) it was further shown that when the model was extended to include a feedback loop the networks could also be trained to perform pattern generation without the need for external stimulation. Nakajima et al. (2013) extended the spring network to a biologically-inspired 3D structure and it was shown that this body could also approximate filters and generate limit cycles. Finally, Zhao et al. (2013) replaced the spring network with the body of a spine-driven quadruped robot, referred to as 'Kitty', and used it to generate both locomotion and its own control signals. This robot stands out because the reservoir consists of force sensors embedded within the spine, the element of the body which is actuated, thereby negating any meaningful distinction between body and control.

In the above examples, morphological computation has been demonstrated to make difficult problems such as locomotion both easier and cheaper. However, filtering, pattern generation, and gait control have a character which is more automatic than cognitive. For example, although different gaits may be programmed into Kitty it is still essentially an automaton - its gait may be robust to some variation in the environment but it is incapable of responding to any stimuli which do not reach its force sensors.

We present the first example of 'minimally cognitive' sensorimotor behaviour arising from a body as physical reservoir. We revisited an experiment introduced by Beer (1996) where an agent controlled by a continuous-time recurrent neural network (CTRNN) was shown to be capable of discriminating between objects of different shapes

through active perception. We replaced the CTRNN with a pair of networks based on those introduced by Hauser et al. (2011) and used an evolutionary algorithm to search for valid controllers.

This section has given the theoretical background and introduced the experiment reported upon here. The next section will describe the experiment and the spring network implementation. We will then describe the results obtained before closing with discussion of the results and some future directions for the work.

Methods

Methods are described in three subsections. First the experiment is described, in terms of the agent-environment interaction. Secondly the spring network, the agent's computational core, is described. Finally details of the evolutionary search for valid controllers are given.

The experiment

The simulated experiment is closely based on that described by Beer (1996, 2003). The required behaviour is to dynamically discriminate between a circular object and a diamond-shaped object. Discrimination is manifested as catch and avoidance behaviours for circles and diamonds, respectively. The arena is an area of 400 x 275. Circular objects are of diameter 30 and diamonds have side length 30.

Objects fall straight down from the top of the arena towards the agent with speed 3. In theory both behaviours are tested for at 24 equispaced points in the x-axis interval [-50,50]. However, the use of a symmetrical controller means that only the left-hand 12 tests need be conducted as behaviour on the right-hand side is identical to that on the left. The agent has an antagonistic motor pair aligned to the horizontal axis. The network outputs set the two motor speeds, and the agent's velocity along its axis is the sum of the two opposing motor outputs. The transfer function for the motor pair is given by:

$$5(\sigma(s_r + \theta_r) - \sigma(s_l + \theta_l)) \tag{1}$$

$$\sigma(x) = 1/(1 + e^{-x}) \tag{2}$$

Due to the use of the logistic function σ , each motor saturates at 0 for its minimum and 1 for its maximum. This and the use of a multiplier of 5 for the result of the sum specifies a horizontal velocity in the range of [-5,5]. θ is a constant value which biases the motor activation point.

The agent's sensors are 7 rays uniformly spaced across an angle of $\pi/6$ and centred about the vertical axis. The sensor transfer function is an inverse linear one between the distances of 220 and 0, with its output in the range [0, 10]. Objects are not detected beyond distances of 220. To reduce evaluation time the sensor model was used to construct lookup tables which were then used in the simulation. The

sensor neuron activations lag behind the values of the linear function, as determined by the sensory layer function:

$$\tau_i \dot{s_i} = -s_i + I_i(x, y) \qquad i = 1, \dots, 7,$$
 (3)

where s is the sensor neuron activation, τ is the time constant for the sensor response, I is the sensor function, and (x,y) is the distance vector from sensor to object.

Network states, sensor activations and the position of the agent are all integrated using the forward Euler integration. As in Beer's original experiment an interval of 0.1 is used to integrate sensor activations and the agent's position. In their experiments Hauser et al. used an interval of 0.001 and made use of a solver function to integrate the spring network activity. However the computational cost of such an approach is problematic when evaluating large numbers of candidate controllers in evolution, so a compromise was made here. We found that an interval at least as small as 0.01 is required to achieve stability in the spring model with the parameters used here, so the spring network is integrated 10 times for each 0.1 interval.

Spring networks

Although the elements in these networks are in fact modelled mass-spring damper systems, for the sake of convenience they will henceforth be referred to simply as springs.

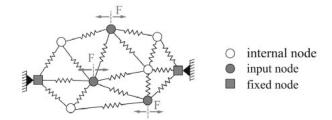

Figure 1: A spring network. The nodes at the opposite ends in the x-axis are fixed while the others are free to move. Some or all of those nodes receive an input as a force in the x-axis. Adapted from Hauser et al. (2011)

The spring networks used here are based upon those in Hauser et al. (2011), illustrated in Fig. (1). The springs are connected to each other in a 2-dimensional plane. Effects such as gravity and friction are neglected in order to simplify the model. The two outermost nodes in a selected axis are fixed while the rest move freely. A subset of the free nodes receive inputs in the form of applied forces. Input forces are applied in a single axis, although this is also for simplification and is by no means a requirement of the model. Reservoir elements were modelled as non-linear springs, defined by the state equations:

$$\dot{x_1} = x_2 \tag{4}$$

$$p(x_1) = k_3 x_1^3 + k_1 x_1 \tag{5}$$

$$q(x_2) = d_3 x_2^3 + d_1 x_2 (6)$$

$$\dot{x_2} = -p(x_1) - q(x_2) + u, (7)$$

where x_1 is the spring extension, k_1 and k_3 represent linear and non-linear stiffness coefficients, respectively, d_1 and d_3 represent the corresponding damping coefficients, and u represents an input force unused in this experiment. In this work we followed the network model of Hauser et al. (2011) in all respects except that the above nonlinear spring model was not used in all networks. In some networks a linear second order spring model was used, with the state equations:

$$\dot{x_1} = x_2 \tag{8}$$

$$\dot{x_1} = x_2$$

$$\dot{x_2} = -\frac{k}{m}x_1 - \frac{d}{m}x_2 + \frac{1}{m}u,$$
(8)
(9)

where k is a stiffness coefficient, d is a damping coefficient, m is the mass on the end of the spring, and, as in Eq. (7), uis an unused input term. For convenience all nodes are given m=1kg. This means that, from Newton's second law of motion, F = ma, forces and accelerations may be treated as equivalent in this network model and Eq. (9) is simplified to a form similar to Eq. (7).

At the beginning of each simulation step the spring extensions are obtained by calculating the distances between the nodes they connect. The rates of change of spring extensions are estimated by the difference between the current extensions and those at the previous step. From these states the instantaneous forces applied to the nodes by the springs can be found, by the use of either Eq. (7) or Eq. (9). The spring forces and input forces are then summed for each node, and the node positions are updated by integration of the resultant accelerations.

Inputs are applied to nodes as horizontal forces, as shown in Fig. (1). In this experiment each network had a total of nine nodes, with two fixed nodes and seven free nodes which each received an input from one of the sensor neurons (see Fig. (2)). An untreated input range of [0, 10] from the sensor neurons was found to give poor results, and so the sensor neuron outputs were scaled and shifted to be in the range [-0.5, 0.5].

The spring network output is a weighted sum of the extensions and extension rates of change of all springs in the network. There is a small departure from Hauser et al. (2011) here. We use the spring extension in the output sum where they used the overall length. The outputs of the two networks are fed into the motor function Eq. (2) in the same way as the CTRNN motor neuron outputs were in Beer (1996).

The CTRNN controller in Beer (1996) was bilaterally symmetric. In this case symmetry of control is achieved by having two identical networks of springs, one of which receives its inputs from the sensory neurons in the reverse

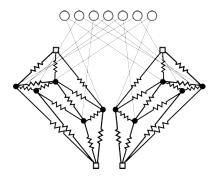

Figure 2: The symmetrical network pair. Two identical networks are connected to the sensor array in opposite orders. The outputs of the two networks are linear sums of the spring states, converted into agent velocity by the use of Eqn. (2). Some nodes and springs are omitted from this diagram for

order to the other. The CTRNN controller consisted of a layer of five fully interconnected recurrent interneurons, and two feedforward motor neurons. The spring network pair replaces these seven neurons.

Searching for solutions

Some network parameters are generated randomly and others are set by a search with a Macroevolutionary Algorithm (MA) (Marin and Sole, 1999). The MA was selected over a Genetic Algorithm (GA) because it was found to be less prone to premature convergence to local optima in the search space for this task. The algorithm was implemented as described in (Marin and Sole, 1999), except for the setting of the two dynamic constants, ρ and τ . The genetic radius for reproduction, ρ , was set by the function $\rho = 0.3(1 - f_{max})$, subject to a minimum value of $\rho = 0.1$. The temperature parameter, τ was set by the function $\tau = (1 - f_{max})$, subject to a minimum value of $\tau = 0.2$. In addition, a constraint was set such that at least one of each generational offspring was randomly generated, in order to promote diversity in later stages. For the same reason, a mutation operator was added such that on average one gene per genotype would be mutated. Mutated genes are moved by an amount in the range of $\pm 10\%$ of the total genetic interval with a probability of 0.9, and replaced with a random value with a probability of 0.1.

A single network topology generated at random at the beginning of each run of the MA is employed by all members of the population. The node coordinates are generated randomly in an area 10 x 10, and then connected with springs by the use of a Delaunay triangulation (Lee and Schachter, 1980). The use of this triangulation method tends to maximise the triangle angles, but also leads to a variable number of springs in the network. Parameters which may be determined by the search are: spring coefficients for stiffness and damping, weights on the sensory inputs to the networks, weights on the spring states for the linear readout, feedback gains, and the bias term for the motor function in Eqn. (2).

For the purpose of evaluation the horizontal distance, d_i , between the agent and the object is clipped to a maximum of 45 and then normalised between 0 and 1. For a catch trial the controller scores $1-d_i$ and for an avoid trial the score is equal to d_i . The final score for a controller is the mean of its individual trial scores. The horizontal distance is clipped to prevent success in one behaviour from dominating a controller's score at the expense of the other.

The MATLAB IDE (The Mathworks, Inc., Natick, MA) was used for all aspects of agent simulation, evolution, and later analysis.

Results

Results are presented in the following order: first, details are given of the performance of the evolutionary search for valid controllers. Secondly, we show some of the inner workings of the network and briefly examine its capacity for memory. We end this section with analysis of two networks by viewing the impact on performance of various lesions.

Searching for solutions

A set of controller features may be enabled or disabled at the beginning of each evolutionary run. These features are: whether to use the linear or non-linear spring model, whether to use spring velocity in the linear readout, whether to evolve real-valued weights on the inputs, whether to use a single random set of spring parameters across the population or to evolve those parameters, whether to employ node position feedback and whether to evolve or to use a constant value for the motor bias in Eqn. (2). The ranges of all evolved parameters are given in Table. (1).

Parameter	Upper limit	Lower limit
Position	10000	-10000
Velocity	10000	-10000
Input weights	-2	2
Linear stiffness coefficients	1	100
Linear damping coefficients	1	100
Non-linear stiffness coefficients	100	200
Non-linear damping coefficients	100	200
Motor function bias	-5	5
Feedback gains	-1	1

Table 1: Limits placed on evolved values.

When node position feedback is employed it is applied as an xy force vector based on a node's displacement from its resting position. Where the motor bias is not evolved a constant value of 2.5640, taken from a successful CTRNN controller which was found when developing the simulation, was used. Where input weights are not evolved, one set of weights is randomly drawn from the set $\{-1,1\}$, and applied to the entire population. These unity weights are of

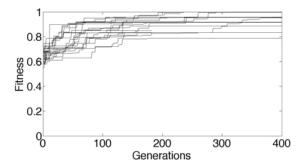

Figure 3: Performance of the MA for a configuration matching controller A, over evolutionary runs of up to 700 generations with a population size of 400. Runs were cancelled when they were either successful or effectively halted. Only the first 400 generations are shown here.

both signs in order to avoid the entire network being pushed in a single direction. When spring parameters were not evolved they were randomised as reported in Hauser et al. (2011). Non-linear spring coefficients are drawn from a uniform distribution in the interval [100,200]. Linear spring coefficients are drawn from a log-uniform distribution in the interval [1,100]. The use of the log-uniform distribution biases samples towards the lower end of the interval.

It was initially unclear which configuration of features was most appropriate, so a set of 20 evolutionary runs, each with a single randomly generated configuration applied across the population, was executed. A population of size 400 was evolved over a short run of 100 generations. It should be pointed out that the MA favours larger populations, but also that the number of the population replaced, and therefore requiring evaluation, upon each generation is variable and typically much less than the population size.

Controller	A	В	С	D	Е
Fitness(%)	99.6	98.9	99.5	98.4	97.8
Number of springs	20	18	18	18	18
Velocity	1	1	1	0	1
Weighted inputs	1	0	1	1	1
Evolve springs	1	0	0	0	1
Nonlinear springs	1	0	0	1	1
Bias motors	1	0	0	0	0
Feedback	0	1	0	1	1

Table 2: Winning combinations. The features of velocity in the readout sum, weighted inputs, evolved springs, nonlinear springs, evolved motor function bias and node position feedback are all optional. 20 evolutionary runs of 100 generations with a population size of 400 were run with random selection of optional features. 5 runs generated successful controllers; each with a unique configuration.

A success threshold of \sim 98% of the perfect score was

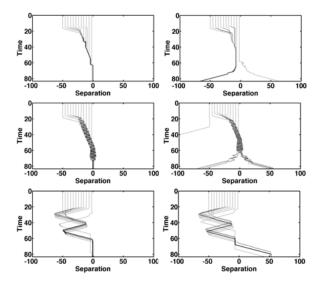

Figure 4: Agent trajectories throughout trials. Trajectories from catch trials are shown on the left and those from diamond trials on the right. Trajectories from three controllers are shown. From top to bottom, controllers A, C and A1.

determined to be sufficient to ensure the correct behaviour, and 5 out of 20 runs resulted in viable controllers. Table. (2) shows the configurations of these 5 controllers. Although this is a small set of results, the variety is striking - the configurations of controllers A and E are similar, but otherwise there is no evidence of a particular configuration which is required for success. However it can be seen that the use of velocity in the linear readout is favoured; being used in 4 out of 5 controllers. Of the remaining features only whether or not to evolve the motor bias stands out; selected in only one result.

Following these results a further 20 evolutionary runs were executed with the arbitrarily selected configuration of controller A. In this case runs continued until the search could be seen to either have succeeded or effectively halted at a local optimum. In this case 4 runs succeeded although others came close. Fig. (3) shows the progress of these runs across the first 400 generations. As yet it is unclear as to whether the difficulty of the problem or the character of the MA is more responsible for the number of failures. However, since evolutionary search is merely being used as a method to find a viable solution, and it readily finds several in our batch runs, its efficiency is not a major concern at present. One of this second set of results, referred to as A1, appears in figures and analyses throughout this section.

Successful networks have proven to be diverse in their topologies as well as their configurations. As shown in Fig. (5) success does not seem to require any particular form of network.

Finally, from a high-level point of view, it can also be seen

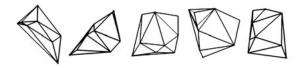

Figure 5: Network topologies of successful controllers. Controllers A through to E are shown from left to right.

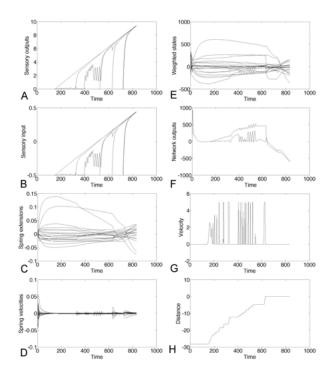

Figure 6: Plots of inputs, states and outputs of controller A from a catch trial. All plots are over time. Plot A shows the outputs of the sensory neurons. Plot B shows the shifted and scaled sensory input to the networks. Plot C shows the spring extensions of one network. Plot D shows the spring velocities of the same network. Plot E shows the weighted positions added to the weighted velocities. Plot F shows the outputs of both networks. Plot G shows the velocity of the agent. Plot H shows the distance between the agent and object in the x-axis.

that various different strategies are possible. The trajectories of controller A, C and A1 for all 24 trials are shown in Fig. (4). Controller A inches towards objects until it can distinguish between them, controller C finds objects quickly and then oscillates around their position until making a decision, and controller A1 scans back and forth.

Network analyses

Fig. (6) illustrates some of the workings of controller A in making a successful catch. As mentioned previously, the sensory inputs are scaled and shifted to the range [-0.5, 0.5].

This has the effect of biasing the network to activity, with the springs already in motion for the first 10s even though the sensory neurons have zero output. The spring extensions and velocities are combined in the readout in this controller. Due to the very large weights used in the readout the network outputs are similarly high. Given that the motor function includes the saturating logistic function, this leads to a motor behaviour of rapidly switching the motors on and off, resulting in the agent creeping incrementally towards the position of the falling circle.

An interesting observation is that as long as the sensory neurons all have zero output, so do the networks. Given that the spring positions are non-zero in this initial period, it is clear that the linear readout is balanced to not respond to this quiescent activity. This is perhaps appropriate to reactive behaviour, but the possibility remains for evolution to lead to a more proactive search strategy by generating an imbalanced readout.

We next turned to measuring the memory of the network following a method based on that described by Maass et al. (2004). Maass et al devised an input stream with zero mutual information (and therefore also zero correlation) between different segments. Then, to obtain a measure of network memory, readout neurons were trained to reproduce segments of the input stream from earlier periods, and segments of the output signal were correlated against the input segments they should have reproduced. A similar approach is taken here, although we chose not to measure general memory capacity but rather to see if these networks can retain information of the inputs they are evolved to deal with. For this reason the readout was trained to recover the simplest combination of the input signals over the course of a single trial, their sum into a single time series. In this case many segments of the input stream have high correlation with one another as, due to the tendency of agents to position themselves under an object until it can be recognised, the general trend is for sensory input to increase as a ramp. Therefore, as a baseline, the same series of correlations was performed for input segments against one another. Where the readout shows no more correlation with earlier input stream segments than its corresponding input segment does, then there can be considered to be no memory. On the other hand, a stronger correlation between the output of the readout and the delayed input it is trained to reproduce than between input and delayed input is indicative of memory in the network. The same test is performed for readouts which receive only spring extensions as inputs, readouts which receive only spring velocities, and readouts which receive both.

The results of some of these tests are shown in Fig. (7). It can be seen that, in general, spring extensions encode more relevant information than spring velocities, but that the combination of the two encodes more than either alone. Controller A shows no convincing sign of memory. For the avoid

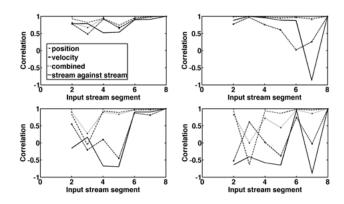

Figure 7: Measuring memory. The linear readout is trained to recover inputs from 10s ago. Then the input stream and the controller output are split into 10s segments and the correlation of each output segment with the prior input segment is calculated. Plots on the left are from a single catch trial and those on the right are from an avoid trial. The results for two controllers are shown. The top row is for controller A, and the bottom row is for controller A1.

trial there is a period where the correlation of input segment against input segment is of the opposite sign to that of readout segment against input segment, but the magnitudes are roughly equal. This seems consistent with the behaviour of this controller. As shown in Fig. (4) for both catch and avoid behaviours, initially this controller gradually creeps towards the object as it falls, suggestive of a purely reactive network. The result for controller A1, however, does indicate a degree of memory effect, with the network being able to recover more information about earlier input segments than the input stream itself. Once again, this is consistent with the general strategy - unlike other results this controller drives away from the object and then returns to it, a behaviour which seems of a more proactive character and implies memory of at least which side of the agent the object is on. It should be pointed out that this controller does not make use of feedback. Any present memory is only transient, fading mem-

Analysis of a network with such complex dynamics in a sensorimotor loop is far from trivial, but a certain amount can be discovered by recording changes in behaviour as parts of the network are disabled. Four experiments, illustrated in Fig. (8) for two controllers, were conducted. In the first three experiments changes were made to the springs, one at a time, and the performance scores for the modified network for all 24 trials were recorded. In the fourth, one input at a time was disabled and the performance scores were recorded. In order, the modifications for springs were: to disconnect them from the linear readout, to remove them from the network completely, and to disable their non-linearity.

Various observations can be made from these plots. It

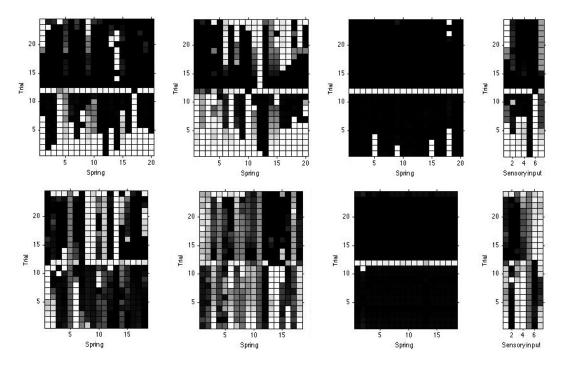

Figure 8: Lesion experiments. The top row of plots shows results for controller A and the bottom for controller A1. The rows in plots show the performance on a trial by trial basis. The brightness of a grid element shows the effect of the lesion. Black regions show unaffected performance and lighter regions show impaired performance. Trials 1 to 12 are catch trials and trials 13 to 24 are avoid trials. From left to right: one spring at a time is disconnected from the readout; one spring at a time is removed from the network, one spring at a time is linearised; one input at a time is disconnected.

can be seen that adjustments to the network for controller A tend to cause failure in catching circles far more often than in avoiding diamonds, as though this controller is predisposed to avoidance. To support this conclusion, this agent also shows low dependence on all but the outermost sensors for avoidance. Complete removal of springs from the network causes a lot of failure in both agents. This is no surprise, given the tightly coupled nature of the network dynamics. Neither controller shows a strong dependence on spring non-linearity,

The plots in Fig. (8) suggest that for both of these agents the most difficult trial is the last where catching behaviour is required. This is surprising as at the beginning of this trial the object is only slightly offset from the agent's position. The reason for this has not yet been properly uncovered, but it seems probable that it is connected to the large weights in the linear sum as relatively small differences in sensory input are amplified into high velocity, which could lead to a sudden loss of the object's position.

Discussion

Discussion of results

The CTRNN described by Beer (1996) was bilaterally symmetric and fully interconnected in the interneuron layer.

Symmetry is achieved here by the use of a pair of identical networks, coupled only indirectly by their roles in the sensorimotor loop. The overall behaviour of the agent is therefore the result of complementary activity in the two sides of the simulated body.

Successful agents obtained by evolution pass the bar for autonomous task-based behaviour, capable of both responding directly to stimuli and making use of short-term memory to guide their motion. The behaviour of these agents goes beyond the maintenance of locomotive gaits to the selection of an appropriate action based on active integration of sensory information. This more complex behaviour is also achieved with a relatively small number of springs. Hauser et al. (2011) used a network of 78 springs; these controllers contain approximately 40.

The morphological computation evident in the tendon network of the human hand is a striking example of parsimony in evolution. This work lends support to the hypothesis that bodies can be and will be doing some of the computational work which used to be considered the sole dominion of the central nervous system.

The use of an evolutionary algorithm to obtain valid controllers has led to strong indications that the domain of these networks is rich in its variety of computational resources.

This potential for diversity may have been less apparent if a learning algorithm was used.

Magg and Philippides (2006) have already shown that this problem may be solved with a non-dynamical ANN, and, as in controller A, it appears that most results seen so far employ little or no memory. However, controller A1 is an interesting result which does seem to rely on memory and suggests that behavioural tasks of a more challenging character than this one may therefore also be addressed with similar spring networks.

Further work

The very large weights used in the linear readout sum tend to lead to the agent switching between extremes of velocity. In a real-world system this would be inefficient and probably lead to shortened motor life. At present we are examining how far the scale of those weights may be reduced while still achieving valid controllers. First results are encouraging, with signs of smoother behaviour.

The results obtained so far indicate that due to the tight coupling throughout the networks they will not fail gracefully when damaged, as indicated in Fig. (8). However, it may be that a damaged network may be easily retrained to recover its function. In future work we will examine the efficacy of retraining by submitting impaired controllers back to evolution.

Although enough good and varied results were found to convince that these paired networks may be used to effect reactive behaviour, efforts are underway to both improve and tune the evolutionary algorithm in use and to make the networks more evolvable. As far as the second point goes, one feature of the problem which has not yet been placed under evolutionary control is the network topology. We believe that topological design by evolution will lead to an improved success rate.

Later projects will explore the capability of spring networks to generate behaviour in compliant robots, and to deal with real-world, noisy, situations.

Hormonal modulation of development and behaviour permits a robot to adapt to novel interactions

Abstract

Hormones are known to play a critical role in modulating the behaviour and development of organisms when confronted with different environment challenges. In this paper we present a biologically plausible hormonal mechanism that allows an autonomous robot to interact appropriately with novel objects and interactions depending upon both its current internal state and its past experiences. In our experiments, robots that had been exposed to negative experiences during their initial developmental phase displayed withdrawn behaviour and were less likely to explore new objects and environments, or to engage with a human caregiver. In contrast, robots with a positive upbringing showed much greater levels of outgoing behaviour such as exploration and social interaction.

Introduction

Hormones have been established as critical behavioural modulators for many types of organisms ranging from vertebrates (leRoith et al, Montoya et al 2012) right through to simple unicellular organism (Kabara 1988) highlighting them as a potential fundamental aspect of life. Like in biological organisms, hormones have also been demonstrated to have a potentially critical role to play in autonomous robots. In these artificial models, hormones have been utilised to successfully modulate different action selection mechanisms in order to achieve appropriate behaviour in a range of scenario (Avila-García & Cañamero, 2004, French & Cañamero 2005, Blanchard & Cañamero 2006, Chelian et al 2012, Krichmar 2013). In our own previous studies (see Lones & Cañamero 2013 & Lones et al 2013 & Lones et al 2014) we integrated hormonal modulation of a homeostatic system through an epigenetic mechanism, in which hormones were secreted in relation to homeostatic deficits. This mechanism enabled a sensory-driven autonomous robot to adapt successfully to a wide range of different environmental challenges and gave rise to the emergence of unique behavioural characteristics.

In this paper, we look to improve the adaption capabilities of an autonomous robot by endowing it with an hormone signalled epigenetic mechanism that modulates the development of a wide range of survival-related and social behaviours as a function of both its internal state and the environmental conditions, and that would permit the robot to interact appropriately with novel objects in its environment. We do this by adding two new hormones to our previous system, functionally akin to two chemical modulators, the steroid hormones corticosteroids and testosterone.

In biological organisms both hormones have long drawn particular interest for their role in modulating a wide range of value-laden survival and social behaviours. This occurs due to the interaction between the hormones and one of their primary targets, the amygdala (Koolhass et al., 1990). While the exact mechanisms are unknown, once the hormones have reached the amygdala, their behaviour is better understood. Testosterone is linked to promoting outgoing reward-seeking behaviours such as dominance, aggression, exploration, and curiosity (Daitzman & Zuckerman, 1980, Mazur & Booth 1998). In contrast, corticosteroids are related to avoidance and withdrawal behaviours (Buss et al., 2003; Montoya et al., 2012). Moreover, these hormones do not only modulate emotional processing of the amygdala but are also believed to affect its neural connectivity to other areas of the brain, particularly the orbitofrontal cortex. Exposure to corticosteroids leads to strengthening these neural connections, while testosterone weakens them (Mehta, 2010; van Wiggan et al., 2010). As the orbitofrontal cortex is associated with decision making, strengthening or weakening the emotional input from the amygdala could result in additional behavioural modulation (Bechara, 2000)

Although the two steroid hormones have significant potential to modulate behaviour, actual studies into the individual roles of these hormones do not always offer conclusive evidence. This is particularly noticeable in human studies where results are normally limited to observation of subjects, which can even be contradictory. There are at least two likely explanations for this. Firstly, there is significant evidence to suggest that both cortisol (CHT) and testosterone (T) work in tandem to modulate behaviour and it is the ratio or imbalance between both chemicals that is important (Montoya, 2012). For example, in a situation with a high T/CHT ration (high T low CHT) aggression is more prevalent than in a situation

with an equal ratio, even when the T level remain constant (Popma et al., 2007).

Secondly, the effects of hormones and secretion are likely to be subjective. This is particularly relevant for organism with highly complex cognition and neural mechanisms, such as humans. Where aspects such as learning, planning, normative behaviour and beliefs gained through life-long experience will affect "consciousness" and therefore can lead to differences in individual emotional processing (Arnold, 1960, LeDoux, 1993 & Khalin, 1993). However, it is not only the level of neural mechanisms that can lead to subjective hormonal modulation. More recently, evidence has arisen of phenotypical plasticity in the neuroendocrine systems responsible for the secretion and regulation of T and CHT. Changes in gene expression occurring within these neuroendocrine systems are known to be associated with extreme forms of behaviour (Mcgowan et al 2009). However, it is also highly likely that these changes could have an effect on day-to-day behaviour.

The neuroendocrine systems of T and CHT consist of the Hypothalamic-pituitary-gonadal axis (HPG-Axis) and the Hypothalamic-pituitary-adrenal axis (HPA-Axis) for T and CHT secretion respectfully. While these two axes are often considered separate entries, they are interconnected through feedback loops. Specifically, research has shown that the HPA-Axis supress the activity of the HPG-axis on all levels. In addition the HPA-AXIS contains a negative feedback loop that consists of glucocorticoid receptors which, in response to rising corticoid levels, signal for the suppression of the axis activity (Montoya et al 2012).

However, this is not a simple static relationship between cortisol levels and HPA activity. Research has suggested that the glucocorticoid receptors responsible for the feedback are susceptible to *epigenetic changes* consisting of upwards and downwards regulation. Downwards regulation, which is a reduction in the total number of receptors, leads to reduced sensitivity to corticoids and thus weakens the negative feedback loop. In contrast, upwards regulation leads to an increased number of receptors and therefore increased sensitivity and a more reactive negative feedback loop (Liu et al 1997 Mcgowan et al 2009, Zhang et al 2013).

Downregulation of glucocorticoid receptors has been linked with, and believed to be triggered at least partially by, continuous high levels of corticoids in the system (Mcgowan et al 2009). Upregulation, on the other hand, has been associated with positive upbringing and experiences during early life with dopamine considered a potential chemical trigger (Liu et al 1997). Much like many other forms of epigenetic changes organisms tend to be more susceptible to mechanism during critical periods of development (Reik et al 2001).

In this paper, we present a hormone-driven biologically plausible robotic model of these mechanisms. Like in the

biological examples discussed, in this artificial model hormones play a critical role in short-term modulation of both the internal environment and the connectivity of different "neural functions" of the robot. This is achieved by secreting the hormones as a function of the robot's internal state and external stimuli, creating a "chemical soup" that surrounds the robot's neural functions. Each "neural function" has receptors that can detect the concentration of specific hormones and are susceptible to modulation accordingly. In addition, hormone levels are also used to signal epigenetic changes in specific areas of the model during critical developmental periods, causing long-term implications on the behaviour of the robot arising from specific characteristics of its internal state and of the environment stimuli that it was exposed to during the critical developmental period.

Robotic model

To test the viability of the previously described mechanism experiments were run utilizing the koala II robot. We added a webcam to the standard robot configuration, which consists of 14 IR range sensors. Control of entire model was handled through a serial connection to a computer running Ubuntu, the architecture was programmed in C++, and openCV was used for vision and image processing. Vision was used to detect resources based on predetermined characteristics such as shape and colour.

As we will discuss in more detail later, we conducted experiments in a noisy environment in open space in our lab. Due to this addition of noise we found it essential to add two functions between the IR-sensors and the Action selection mechanism. The first function consisted of a form of sensory memory similar to iconic memory in which information from IR's are briefly stored before decaying.

$$\begin{cases} Tsv_{i\,t} = \frac{sv_{i\,t-1}}{r_D} & if \ sv_{i\,t} < Abst_i \\ Tsv_{i\,t} = \ sv_{i\,t} & otherwise \end{cases} \tag{1}$$

where Tsv is total IR sensory value which is passed to the ASM, sv the current sensor value, i is sensor number, t time, rD is the rate of decay which was set to make sensory information fully decay in just under a second, and Abst the absolute threshold that defines the minimum value that sensors need to become 'active'. The second function heightens the sensitivity of sensors neighbouring an active sensors by reducing the Abst by heightened value (hV) which is equal to 33%

Homeostatic variables

The architecture of the robot includes three survival-related variables which are homeostatically controlled: health, energy and temperature. These decrease as a function of the robot's actions and interaction with the environment. Whereas 'health' is simulated, the two other variables are linked to the actual physics of the robot. When the robot detects contact of significant strength, its homeostatic variable 'health' decreases proportionally to the size of the force. This deficit can be recovered by finding and utilising a repair resource. Energy is linked to the robot's battery, which has a maximum capacity of 3.5 ah (3500 mAH), permitting around 4 hours of usage. Due to the long battery duration, to make the environment more challenging, the architecture was programed to allow the robot sense a maximum of 75 mAh of charge at any time, equivalent to a running time of around 5 minutes at a moderate activity level. Consumption of an energy resource increases the charge available to the potential maximum of 75 mAh. Finally, temperature is related to the speed of the motors and directly sensed using the internal temperature monitors of the robot. Each of the survival-related homeostatic variables has a lethal boundary which if transgressed results in the agent's death. In the case of energy and health, the lethal boundary is set at the bottom end of the range of permissible values, in the case of temperature the lethal boundary is at the upper end of the range.

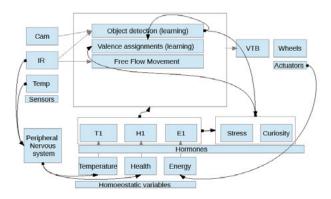

Table 1 the homeostatic resources

Homeostatic Variable	Energy	Health	Temperature			
Derived from	Battery level	Simulated	Internal sensors			
Range	0-75 mAh	0-100%	26–32 degrees			
lethal boundary	0 mAh	0%	32 degrees			
Deficits	Semi- dynamic	Dynamic	Dynamic			
occurrence						
recovery	Energy	Health	Reducing			
	Resource	Resource	motor speed			

Action selection architecture Mechanism (ASM)

The robot's action selection architecture consists of three main internal systems: object and stimuli detection, valence assignment and free flow movement. Behaviours emerge from the activation, interaction and modulation of the different internal systems, rather than being pre-determined.

Figure 1: Action selection architecture used in this paper.

Object detection is achieved by a combination of image and IR data. Data from the camera is processed (using the openCV library) to detect resources scattered around the environment. The IR sensors feed into a learning growing artificial neural network in order to detect and classify novel objects. The latter uses primarily information about the size of objects, determined by the number of IR sensors active. Since this type of neural network needs a very long training phase to learn from scratch, for the experiments presented in this paper we trained the network off-line; the same network was used for all runs

Table 2 The types of objects the IR sensors can detect

Number of sensors active	Type of object
0	Empty space
1	Small object
2	Medium sized object
3	Large object
4+	Wall
0, but both neighbouring neurons active	A hole or gap

As well as being able to classify different objects into size groups, a second function of this system is to *predict* the behaviour of a detected object in terms of how close or far it will be at the next point in time, or which sensors might detect it next if it is being passed. Each IR sensor can store up to three predicted locations at any one time – those generated by itself and by its two neighbouring sensors. Since, as we will see later, the environment is primarily static, the robot will always assume any change in distance to be the result of its own movement. For example, while moving forward, an object that is detected in front of the robot will be expected to be closer, while an objected detected on the left will be expected to be later detected by an IR sensor on the same side but further away in the direction of motion, and therefore the predicted location of this object is shared with this sensor.

Figure 2: Object prediction system. The distance to the predicted location is determined by a range of values between two boundaries, which are calculated as follows:

$$upperBoundary_i = Tsv_i + oS_k + sP_i + H_c - H_s$$
 (3)

$$lowerBoundary_{i} = Tsv_{i} \frac{upperBoundary}{1 + (\frac{4}{sP_{i}})}$$
 (4)

where sP_i is the speed at which the robot is moving towards the object, oS_k the expected object speed (always 0 in this case as objects are expected to be stationary) the current concentration of stress (H_s) and curiosity (H_c) hormones

The width of the predicted area (if the prediction is passed on to a neighbouring sensor) is determined by

$$\begin{cases} passed \ to \ left \ \ if \ \ \frac{lWSpeed}{rWSpeed} \ + oS_k > dS_i \\ passed \ to \ right \ \ if \ \ \frac{rWSpeed}{lWSpeed} \ \ + oS_k > dS_i \end{cases} \tag{5}$$

where IWSpeed and rWSpeed are the speed of the left and right wheels, respectively and dS_i is the distance between neighbouring sensors, which is unique between each pair.

If no object is detected by a sensor or its neighbours, then the robot will only expect to detect distant objects. If an object is detected outside the predicted area, e.g., if an object is placed directly in front of the robot, it will be perceived as unexpected and treated as a stressor.

Valence assignment occurs after an object has been detected and its value depends upon both the type of object and the current internal state of the robot. Valence is an emotion dimension associated with objects, interactions or events (Russell, 1980; Posner et al, 2005) and that provides values along a pleasure-displeasure continuum. The value of objects is calculated as a function of the potential threat associated with the object, and the internal state of the robot. The base valence for a novel object (V_o) is determined as a function of their size – larger objects are perceived more negatively as they could potentially be more dangerous,. The internal factors contributing to valence are the current concentration of stress (H_s) and curiosity(H_c) hormones. The effect that these hormones have on the perception of different objects scales differently (S_{oh}) for each object as shown in table 3.

$$valence = V_o + (H_s S_{os}) + (H_c S_{oc})$$
 (6)

Table 3 Valence detection

Type of object	Initial	Curiosity	stress
	Valence	scale	scale
Empty space	1	1	-1
Small object	200	2	-4
Medium sized object	-200	8	-8
Large object	-400	14	-12
Wall	0	-2	10
A hole or gap	-800	20	-16

Hormone model

The epigenetic artificial hormones in this model consist of two main groups, that we have named "endocrine hormones" (eH) and "neuro-hormones" (nH). While both group types share common characteristics, they also present some significant differences. Firstly, endocrine hormones (eH) are secreted by their respective glands in relation to homeostatic variables deficits. Each variable has an associated hormone – E1 for energy, H1 for heath and T1 for temperature – released by a corresponding gland. The secretion of each of these hormones occurs when the ASM stimulates its associated glands (g_i) as a function of the relevant homeostatic deficit.

$$g_i = x_i \varphi_i^{defict} \tag{7}$$

where x_i is the strength of stimulation from the ASM and φ_i the gland's activity level.

The gland's activity level is determined by a simple biologically plausible epigenetic mechanism akin to epigenetic adaption that we previously implemented in (Lones & Cañamero, 2013) This mechanism consists of a positive feedback loop were high concentration of a secreted hormone will lead to increased gland activity.

$$\varphi_i = \varphi_i + \frac{eH_i}{e^S} \tag{8}$$

where eS is a constant value used to control the speed of the epigentic change.

The secretion of the second group of hormones is triggered by a combination of the robot's external perception of the environment and its current internal state. This hormone group includes two hormones called "stress" and "curiosity". As the name suggests, the stress hormone (H_s) is inspired from the roles that cortisol and serotonin play in regulation of stress responses, and hence it regulates stress response in the robot.

$$g H_s = roD + \left(\frac{oS + F}{x}\right) * fL \tag{9}$$

where oS is overstimulation (a simple addition of all objects detected), F is fear (total value of negative stimuli detected), fL is the feedback loop, and x a constant, roD $(0 \le roD \le$ 1) is the robot self-perceived "risk of death" (Risk of death as a measure of viability was previously developed by Avila-García & Cañamero ,2004) which is derived from the current concentration of the three endocrine hormones. The risk of death is determined by both the current level and duration of any homeostatic deficits. In addition, since hormone concentration is also affected by the previously described epigenetic mechanism, the perceived risk of death will also be dependent on the development of the robot. For example, whereas a robot that is constantly low on energy will likely develop hyper-sensitivity to energy deficits and will end up perceiving a high risk of death when energy deficits occur, a robot that "grows up" in an environment that permits it to always maintain high energy levels will develop a natural tolerance to deficits. The stress hormone is secreted under three types of circumstances: when there is a high risk of death (linked to homeostatic deficits), when there is overstimulation from exposure to different novel objects, and in the presence of perceived threats.

Our curiosity hormone (H_c) takes inspiration from the roles that hormones such as testosterone and dopamine play in regulating (in this case increasing) behaviors related to dominance, aggression and curiosity.

$$g H_c = \frac{(1-roD) + \left(\frac{R+pS}{x}\right)}{1+H_S} \tag{10}$$

As can been seen, H_c secretion occurs with low risk of death, perception of interesting objects (pS), and as homeostatic deficits are recovered (R). In addition, the concentration of H_s limits the secretion of H_c in a similar manner to the biological interaction between cortisol and testosterone through the HPA axis. Much like the HPA axis found in biologically systems, an epigenetic mechanism exists in our artificial HPA negative feedback loop. In biological systems, this mechanism consists of glucocorticoid receptors present at both the hypothalamus and the anterior pituitary lobe of the pituitary gland. These receptors detect the current concentration of corticosteroid and lead to a negative feedback loop if levels are too high (Liu et al 1997 Mcgowan et al 2009, Zhang et al 2013). An important feature of these receptors is that they are susceptible to epigenetic changes in gene expression. Exposure to constant high levels of corticosteroids, for instance, leads to downregulation in the feedback loop (Mcgowan et al 2009). However positive environmental upbringing has shown to lead to upregulation. While the exact mechanic of upregulation is unknown, exposure to hormones/neuro transmitters associated with happiness and outgoing behaviour i.e dopamine are potential and realistic mechanism with some supporting evidence (Liu et al 1997). In this model, upregulation and downregulation of the glucocorticoid receptors and therefore the regulation of the feedback loop (fL) are respectively associated with exposure to H_s and H_c .

$$fL = \frac{1}{1 + e^{-(H_S - H_C)}} \tag{11}$$

Once part of the chemical soup (cS_h) all hormones decay at the same rate which in this model was set to 0.95

$$\sum_{h=0}^{4} cS_h = cS_h * 0.95 \tag{12}$$

Experiments

For this paper we tested this architecture under two main experimental conditions: a relatively static environment where the only changes occurred as a result of the interactions of the robot, and a much more dynamic environment that included human-robotic interaction. The environments used for our tests were implemented in the open space of our lab, an area of about 45 m² in which desks and chairs are located near the walls, surrounding an empty central area. The robot could roam freely around the lab that was only modified by removing the swivel chairs and by placing limited plywood boards to protect sensitive or delicate areas. Resources, obstacles and other environmental stimuli were then added as can be seen in figure 3. In all cases, an identical architecture and robot was used for each experiment.

Figure 3: The positive and negative environments. Figure 3 shows two different angles of the environment the positive on the left and negative environment on the right with the differences discussed in more detail bellow

In both experimental conditions ("static" and "dynamic" environments), the tests involved two phases. In the first phase, identical for both experimental conditions, the robot spent its critical developmental period (in our case the first 5 minutes of its "life") in one of the two environments previously discussed, with an equal split between the two types of environments within each experimental condition: either a "positive" or easy environment (half of the runs for each experimental condition) or a "negative" or stressful environment (half of the runs for each experimental condition). As can be seen in Figure 3, both positive and negative developmental environments share similar design with a few subtle but important differences, as follows. A) the first difference is the homogeneity of materials used, with more variation occurring in the negative environment. As IR-Sensors naturally respond differently to different materials. increasing variation naturally leads to more fluctuations in sensor readings. Due to the previous described neural mechanism, these fluctuations are likely to lead to a stress response. B) The second difference is the increased use of objects made of textures and/or colours particularly difficult to detect in the negative environment. Not only does this lead to fluctuations in sensor readings but also, since the robot is unable to accurately detect distance, it also increases the likelihood of collisions. C) The third difference is the spacing between objects. In the negative environment, distance between different objects is small, increasing the potentially for over-stimulation. In addition, smaller spaces in structures like the maze depicted in the figure also hamper navigation significantly, potentially increasing stress. D) The Final, a fourth difference is the "reward" obtained for exploring the environment, which is greater in the positive environment. For example, in the positive environment the reward for completing the maze is an easily accessible homeostatic resource. In contrast, while the resource is still present in the negative environment, the likelihood of finding and accessing the resources, and therefore of getting a reward for completing the maze, is smaller.

The second phase differed for each condition. A set of 10 single-robot runs, each of duration of 15 minutes, took place in relatively static environment, and a set of 10 runs of duration of 5 minutes per run in the dynamic environment. In this second condition, human-robot interaction took place in an empty environment after the robots had developed. While challenges and potential stimuli to explore were still in abundance at the edges of the environment, the centre was largely barren in order to increase the chances that the robot would focus on human interaction. Runs were reduced to 5 minutes since the experimenter could finely control exposure to stimuli, making unnecessary the longer duration of runs that was used in the static environment condition in order to ensure that the robot could fully explore the environment.

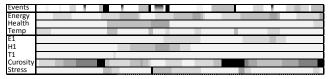

While the ASM was never specifically designed or programed for human-robot interaction, we found that it would naturally lend itself to simple types of interaction. For example, the robot generally found stroking interaction positive as it led to a release of the curiosity hormone, whereas sudden movement usually invoked a fearful or negative response. The robot's response to an action was also highly influenced by the way it was carried out. For example like in (Cañamero & Fredslund, 2000), the speed, force and duration of the stroking motion will have a significant impact on the robot's response The response is again also influenced by a combination of the robot's internal state and developmental history. A robot that has had extensive human interaction was more likely to enjoy vigorous stroking where as one that has suffered extreme deprivation might find displeasure in even minimal contact.

Experimental results and discussion

To analyse the results of our experiments in terms of the performance of the robot, we had initially planned to use the viability-based indicators of performance developed in previous work (Avila-García & Cañamero, 2004.), such as wellbeing, overall comfort, or risk of death. However, due to the epigenetic developmental mechanism in our present architecture, the robots that developed under different environmental conditions developed different tolerance to stimuli and homeostatic deficits. These differences in tolerance led to skewed results using the above-mentioned performance indicators, as will discuss below.

Experiments in the static environment. As can be seen in figure 4, the interaction between the environment and epigenetic hormonal mechanisms made the robot have significantly different behaviours once developed and placed within the "neutral" testing environment.

Internal state of a robot developed in the positive environment

Internal state of a robot developed in the negative environment

Figure 4: The internal state of two robots. Figure 4 shows the internal state of a robot from the positive and negative environments during the 15 minutes in the static environment. Darker colours indicate increased stimuli, higher homeostatic deficits or increased hormones concentrations respectfully.

In all cases, robots that had developed in the negative environment showed a very "withdrawn" behaviour: the robot spent a significant portion of its time executing a behaviour similar to wall following. If the robot found a corner or an enclosed area, it would remain stationary in this location until other internal needs (e.g., the need to replenish energy) became more prioritarian. The reason for stopping in these enclosed areas was likely to be the fact that they were perceived as the safest location - as walls, which, detected on multiple sides, in a stressed state would have positive valence, effectively treating them as nests. As can be seen in figure 4, interaction with other areas of the environment was minimal due to the constant high level of the stress hormone, which suppressed the HPG-Axis effectively, preventing the emergence of a ratio between curiosity and stress that would modulate the ASM into investigating novel objects. In a few rare occasions that the robot did have a high enough level of curiosity hormone to facilitate and initiate interaction with novel objects, it quickly became over-stimulated and reverted to the previous withdrawn behaviour. Stress responses in

regards to interactions with novel objects not only tended to be more prevalent in these robots but also were significantly more severe and lasted on average 60 percent longer. Stress responses and hypersensitivity in regards to homeostatic deficits where also heightened in the robots that developed in a negative environment. Essentially, this meant that the robot would look to maintain homeostatic deficits at a higher level and if they started to drop, the robot would quickly enter it withdrawn behaviour. The implication of this is that, once the robot found an area of the environment with access to both resources, it would tend to stay in that general region and never really explore for new opportunities.

In contrast, the robots that had *developed in the positive environment* showed a much more outgoing behaviour, thoroughly exploring the entirety of the environment and interacting with a large range of the different novel objects. While this outgoing behaviour did lead to increased risks such as collisions or over stimulation, which caused the two high stress moments that can be seen in figure 4, the robot was able to recover fairly quickly. In addition, robots developed in a positive environment tended to have a greater tolerance to homeostatic deficits, which made them spend more time exploring and interacting with the environment.

When comparing the two robots developed under different environmental conditions, one additional significant difference can be observed in figure 4: the manner in which hormones were secreted, which tended towards quick large releases in the robot from the negative environment compared to smaller sustained releases from the robot with positive background. The quick bursts led to more unpredictable but responsive behaviour in regards to environmental stimuli. This could perhaps be compared to a highly responsive "flight-or-fight" system.

Experiments in the dynamic environment. In our second environment, dynamism was introduced by the presence of a human who interacted with the robot. Once again, the robots in the different runs had developed either in a positive or a negative environment. Due to the limited range of the robot's sensors, the range of "recognisable" interactions was relatively small.

As we could expect, the robots that had developed in a negative environment had a "timid demeanour" and tried to avoid any form of human interaction. However, gentle stroking motions along the IR-sensors could be used to initiate interaction by causing a rise in the concentration of the curiosity hormone. Interaction was primarily limited to this slow stroking as well as the robot exploring the human at its own pace. Any sudden movements or overzealous stroking would quickly lead to overstimulation of the robot and an attempt to withdraw. However, even with an ideal level of interaction, the hypersensitivity to homeostatic deficits meant the robot would only spend a maximum of around 30 seconds interacting before becoming more interested in procuring resources. It should be noted that robots that had developed such an aversive phenotype would try to withdraw immediately regardless of the interaction that the human tried to have. In addition, continuing to engage with any of these robots after they had attempted to withdraw led to an "aggressive" behaviour were the robot would attempt to push past or in a few case even turn to face the human and drive into them. We are still investigating the reason behind the emergence of this behaviour; however, we know that, for it to be triggered, the robot needs to have both an extremely high concentration of the stress hormone and a medium to high concentration of the curiosity hormone. Due to the inhibiting relation of the HPA-HPG axis, this concentration mix is a relatively rare phenomenon, and so far has only been achieved in the negative robot. These incidents represented the only time any of the robots made physical contact, excluding accidental collisions.

As we also expected, the robot that developed in a positive environment was much more tolerant of interaction with the human. Slow- to medium-speed stroking led to an initial positive response; after a period of interaction, faster stroking and sudden movements were tolerated and even sparked interest from the robot. To this extent, if an object such as a ball was thrown, the robot would go after it to investigate. Once the ball/object stopped and the robot had explored it as a normal novel object in the environment, the interest in the object would drop, often leading to the robot to return to the human in search of increased stimulation. It is worth noting that the robot did not know who or what had thrown the object and returned to the human purely because s/he is a large moving object and therefore had a high positive valence). As a comparison, an object thrown at a robot from the negative environment almost always led to the robot's withdrawal. An interesting aspect that emerged was the ability of the human to calm down the robot (i.e., to reduce its level of curiosity) by using low stimulation in the interaction.

Conclusion

In this paper we have presented and demonstrated a biologically plausible epigenetic mechanism that modulates the development of a wide range of value-laden survival and social behaviours, taking inspiration from a key component in the formation of motivations and behaviours: the HPA-HPG axis. As this epigenetic mechanism is dependent upon the internal state of the robot and its exposure to different environmental stimuli, the final phenotype of the robots reflects the conditions in which it developed. Our results show that a robot that developed in a negative environment spent a majority of its time thereafter trying to avoid any interaction with anything new or novel, preferring instead to simply stav in a safe location and maximise its homeostatic levels, providing a buffer to help protect itself from it perceived environmental dangers. In contrast, a robot developed in a positive environment spent a large portion of its time interacting with and exploring its surroundings. This included interaction with a human, for which the robot had not been programmed and that emerged as a consequence of the developmental history of the robot. Based upon our results in this paper, we argue that this model can provide a useful adaptive mechanism for autonomous robots to develop

behaviour that allows them to interact appropriately with different elements of a novel (physical and social) environment. In the future, we will look to expand this model by running experiments over longer periods of time and utilising the learning algorithm mentioned in the ASM section. This model will allow us to investigate the potential roles that hormones may play in modulating learning experiences.

Idiotypic networks for evolutionary controllers in virtual creatures

Nicola Capodieci¹, Emma Hart² and Giacomo Cabri¹

¹University of Modena and Reggio Emilia ²Edinburgh Napier University

Abstract

We propose a novel method for evolving adaptive locomotive strategies for virtual limbless creatures that addresses both functional and non-functional requirements, respectively the ability to avoid obstacles and to minimise spent energy. We describe an approach inspired by artificial immune systems, based on a dual-layer idiotypic network that results in a completely decentralised controller. Starting from a system initialised with five non-adaptive locomotion strategies, we show that an adaptive controller can evolve that both minimises energy requirements and maximises distance covered when compared to the initial strategies.

Introduction

In Blumberg and Galyean (1995) a virtual creature is defined as an animate object, capable of goal-directed and time-varying behaviour, situated within a simulated environment with which it can interact. In this paper, we will focus on how to provide the means for a virtual creature to discover adaptive movement patterns; this will be accomplished by applying a previously introduced design methodology that merges artificial immune systems (AIS) and autonomic computing (Kephart and Chess (2003)). AIS takes inspiration from the biological immune system, in order to extract algorithms and methodologies for designing computational systems able to feature the same characteristics of the biological immune system, such as scalability, adaptivity, emerging cognition and decentralization. The evolutionary features able to provide adaptivity in the observed systems depends on which AIS related paradigm is used for solving a specified computational problem (De Castro and Timmis (2002)). In this instance, idiotypic networks as theorized by Cohen (2000a,b) have been used, due to their ability to show cognition. We are going to model our creature as a collection of independent (autonomic) units, with the aim of discovering new trajectories of movement and detect/avoid obstacles while optimizing the energy consumption of the virtual creature. This can be translated into a distributed autonomic computing related problem due to the composite morphologic nature of the creature itself and its requirement to Self-Adapt over time. Adaptation here is seen as the ability of the creature to combine known movement patterns with no adaptive ability in order to evolve new locomotion strategies able to keep the creature in motion. Although there is a wealth of literature related to the use of evolutionary methods for achieving control, our work differs in two key aspects. Firstly, it considers both functional and non-functional requirements of the creature, achieving movement while minimising energy. Secondly, our algorithm (that we name SelfEx) is completely distributed, in that every constituent unit of the virtual creature is able to evolve independently, sharing the minimum amount of information throughout the whole creature. Another difference compared to previous literature is the kind of network(s) involved: using an idiotypic network instead of a neural network (e.g. evolutionary morphologies as in Miconi and Channon (2005)) has the potential to further enrich the literature regarding evolutionary virtual creatures.

The paper is organized as follows: after presenting a review of related work, a description of the components of the virtual creature and its surrounding environment will be provided. The SelfEx approach is presented by detailing the modelling choices used. After the model is presented, all the details regarding the simulations and experiments performed and their related parameters will be given. The paper is concluded with discussions about the obtained results and related future research directions.

Related work

The vibrant field of Artificial life uses computer simulation to investigate evolution of behavioural and cognitive mechanisms in virtual creatures Sims (1994), potentially leading to advances in both biology (e.g. Palyanov et al. (2012)) and robotics (e.g. Černỳ and Kubalík (2013)). We restrict our review to work related to understanding the evolution of movement strategies that might ultimately be applied to the robotic field. A significant volume of work exists in the evolutionary computing literature, summarised by Prez-Moneo Surez and Rossi (2013) in relation to movement of limbless creatures. Typically, evolution evolves centralised

controllers in which performance is evaluated in terms of the evolved trajectory and ability to avoid obstacles but does not account for energy consumption of the movement, a relevant factor if the motion is to be transferred to real robots. Moreover, our approach (SelfEx, named after the Self-* property of a system to autonomously change its coordination pattern during run time execution of tasks (Cabri and Capodieci (2013)) uses a set of pre-coded movement strategies as baseline behaviours to evolve. This is in contrast with known evolutionary controllers in virtual creatures, since these latter ones rely on single atomic actions.

From the robotics perspective, a number of authors have advocated the use of immune-inspired control strategies, beginning with Ishiguro et al. (1995) (autonomous navigation for a single robot). This work was more recently extended by Whitbrook et al. (2010), in which the authors detailed how similar algorithms can be properly transferred in real robots. In Capodieci et al. (2013a), the authors proposed that ideas from autonomic computing could be combined with immune-inspiration to provided distributed control. An idiotypic network algorithm was proposed and applied to selecting movement strategies in swarm foraging task in Capodieci et al. (2013b). The model was formalised into a framework (Capodieci et al. (2014)) but only considered functional requirements.

The creature

The virtual creature used for our simulations is depicted in Figure 1 (left hand side). It is composed of 10 identical constituent units, each a perfect cube shape. Each unit is connected to its neighbouring unit(s) through a chain of universal joints, thus giving them complete freedom to rotate along the X axis, while rotations along the other axes are constrained by collisions with nearby units. The initial spacing between two units is set to one fifth of the length of the cube size. Trivially, the creature is simulated in a 3D environment in which the three axis have the orientation shown in Figure 1 (left hand side) and collision, friction and gravity forces are present. Each unit is completely independent — the only shared variable is an analogous to a biological clock that ensures synchronised adaptation of units. This is depicted in Figure 1 (right hand side) and is represented by a periodic square wave in which we can identify two distinctive phases, labelled as positive (P) and negative (N) phases. The use of a common shared clock is common in the field of virtual robotic creatures in attempting to imitate the oscillatory and periodic locomotion activity cycles of many existing animals (e.g. see Ijspeert (2008) for a survey on the existing methods for implementing Central Pattern Generators (CPGs)). The period of the clock can be adjusted according to T_{eval} .

Movements and related energy consumption

The functional objective of our creature is to keep moving and to discover new means of locomotion. In previous work, movement has been achieved by use of fixed functions, e.g. the serpenoid function as proposed by Hirose and Morishima (1990), applied at junctions on the body. However, this requires the use of an external and centralized controller. In the presented decentralised model, a generic notation for representing a movement pattern is to consider that during each clock phase, each unit independently applies a force from the centre of its mass with magnitude $M_g \leq 1$ with a direction described as a vector in which the unitary magnitude of the force can be distributed among the three axes: $(m_{qx}\mathbf{e_x} + m_{qy}\mathbf{e_y} + m_{qz}\mathbf{e_z})$, given $|m_{gx}|+|m_{gy}|+|m_{gz}|=M_g$ and where $\mathbf{e_x},\mathbf{e_y},\mathbf{e_z}$ are the canonical basis vectors in \mathbb{R}^3 . The direction of each force is always relative to the orientation of the unit. Movement of the creature therefore results from physical interactions between moving units; not all units are required to apply a force (and consume energy) for movement to occur: push or pulling behaviour of a unit can result from a force applied to a neighbouring unit. The energy spent by a single unit during a single time interval is calculated by summing the magnitudes of the applied force in both the positive and negative phase of the clock, therefore a single unit, during a time interval can show an energy consumption in the range [0, 2]. The total energy consumed (related the whole creature as indicated with EnC_{tot}) during a time interval is trivially calculated by summing the energy consumption experienced by each constituent unit during each phase of the clock.

Movement patterns

A series of 5 initial pre-coded movement patterns are used as starting points for evolution. A movement pattern is a description of how the whole creature moves and it is obtained by indicating magnitude and direction of the forces to be applied to each of its constituent unit during each phase of the clock. In the initial pre-coded movements, all forces magnitude are 1 and they are applied to one of the possible directions among $[\pm X, \pm Y, \pm Z]$. These movement patterns are loosely based on how limbless creatures move in space and are summarized in Table 1. In that table, for each unit (identified by a number from 0 to 9), the direction in which the force is applied is shown for each of the five pre-coded movement patterns (from Type1 to Type5). Individual units iterate the application of such forces as described in Table 1 during every time interval. Each initial pattern has an associated energy consumption that is fixed through the duration of an experiment. Moreover, the initial patterns do not enable obstacle avoidance or adaptation to external perturbations that cause unexpected rotations of the unit(s) and thus provide a baseline for evaluating whether these behaviours can emerge.

In Figure 2 the movement pattern labelled as Type1 is rep-

Table 1: Table of initial movements patterns, Type1-Type5, showing force applied to each unit at each clock phase (P,N). EnC_{tot} : total consumed energy during T_{eval} . Example: in the movement pattern Type5, unit 0 applies a force of 1 magnitude over the negative Z axes in the positive (P) phase; no forces applied during the negative (N) phase.

resented and resembles the locomotion strategies adopted by caterpillars. Other movement patterns are based on rolling and crawling, similar to snakes or worms¹. It is important to stress that different movement patterns result in different outcomes both in terms of non-functional requirements (see the last column of Table 1, the total energy consumption EnC_{tot}) and in terms of functional requirements (calculated as the space distance the whole creature managed to travel during a time interval). Regarding the distance travelled by the creature, the performance varies according to the orientation of the constituent units, therefore any perturbation that causes the units to rotate from their original position can drastically change its performance and even prevent the creature to keep moving.

SelfEx: an idiotypic control model

Each constituent unit of the creature is seen as an autonomous component and has an associated $lymphnode\ l_{c_i}$. Each lymphnode is consisting of an internal network of interconnected antibodies. Additionally, an antibody in l_{c_i} may be connected by stimulatory or suppressive links to antibodies inside neighbouring lymphnodes $l_{c_{i+1}}$ and $l_{c_{i-1}}$, forming an $external\ network$. Antibody concentration varies over time according to the process outlined in Figure 3 and 4 and described in detail in the following sections. At the end of each time interval, the unit will select the highest concen-

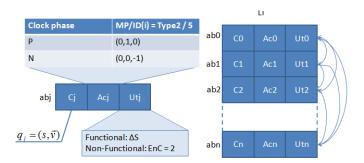

Figure 3: On the left side the model of a single antibody is shown. Example values are given to the action field (as verifiable from Table 1). The right part shows the connections among antibodies inside a single lymphnode.

trated antibody, so to extract from it a computational equivalent to an immunological response. Before describing the details of this process, it is important to show how the virtual antibodies are modelled.

Antibody Representation

An antibody is represented by a tuple $\langle condition\ C, action\ Ac, expected\ utility\ Ut \rangle$ and has an associated concentration (see Figure 3). This generic format was introduced in Capodieci et al. (2013b), and its implementation is application dependent. Here, the condition field is a quaternion in the form (s, \overrightarrow{v}) representing a possible orientation of the cube/unit in the three

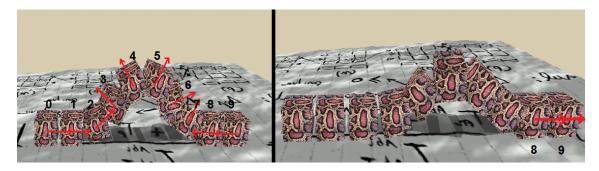

Figure 2: A graphical representation of the movement pattern "Type1". Left part: positive phase P of the clock, Right Part: negative phase N of the clock. Identifiers of the single units are also indicated in this picture.

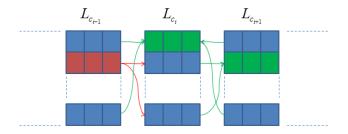

Figure 4: An example situation of how stimulation and suppression signals propagate in the external idiotypic network among three lymphnodes. Green antibodies resulted in positive feedback, while the red one obtained a negative feedback. Green arrows correspond to the increase of affinity by all the other unselected antibodies of neighbouring lymphnodes towards the green antibodies, while red arrows correspond to the increase of affinity by the red antibody towards all the other unselected antibodies.

possible directions of rotation. An *action* is a data-structure that represents a component identifier, the identifier of a movement pattern, and the magnitude and direction of the forces to be applied to the component at each clock phase. Finally, the *utility* field specifies two values corresponding to the expected value of the functional and non-functional measures. ΔS represents the functional utility and is simply the Euclidean distance between the starting position of the unit and its position at the end of a single time interval. The non-functional quantity is the energy consumption EnC (related to the single unit).

Initialisation and pre-experiments

Typically, initial antibodies populations in both AIS and evolutionary algorithms are created randomly. Instead, we seed the lymphnodes of each unit with a population of antibodies from information learned during a pre-experimental phase: each of the movement patterns described earlier are tested for a variable length of time (in terms of multiples of T_{eval}) to determine utility values. During this phase, external perturbations are applied randomly to the creature in order to

obtain a large interval of rotations as condition field of the antibodies. All antibodies are then initialised with concentration c_{init} . In the subsequent sensing phase, in each lymphnode l_{c_i} , the distance between the orientation specified by each antibody in the lymphnode (q) and the current orientation of the unit (q') is determined according to equation 1(a). Within each lymphnode lc_i , antibodies are ordered according to distance and assigned a fitness f_i according to equation 1(b), where ΔS_i and EnC_i are expected functional and non-functional utilities according to the utility field. Using a fitness proportionate selection method based on these fitness values, an antibody is chosen and its action applied to the relevant component (testing phase). It is important to notice that, since this very first step of the algorithm, each unit/lymphnode of the creature can choose actions related to different movement patterns, hence the search for alternative trajectories begins in the first time interval. The testing phase is followed by an evaluation phase in which the adaptation mechanisms take place.

(a)
$$d(q, q') = 2(1 - |q \cdot q'|)$$

(b) $f_i = \frac{\Delta S_i}{1 + EnC_i}$ (1)

Adaptation

This is the adaptation phase in which the original movement patterns evolve to optimise the functional and non-functional requirements of the creature. New antibodies are created that combine and/or adapt components of the 5 initial movement patterns into new strategies (see algorithm 1).

Affinity At the end of the evaluation phase, within each lymphnode, the currently active antibody ab_* (as the last selected antibody) discriminates between situations that lead to positive or negative feedback. Positive feedback is received whenever the obtained ΔS_o is greater or equal to the expected ΔS_{exp} stored in the currently selected antibody; negative feedback is received otherwise. Within each internal network, each antibody $ab \in l$ increases its affinity to ab_* if positive feedback is received. In case

(a)
$$\frac{\Delta c_{i}'}{\Delta t} = K_{p} \sum_{j=0}^{N} r_{j,i} c_{i} c_{j} - K_{n} \sum_{k=0}^{N} r_{i,k} c_{i} c_{k} + K_{D} \frac{d(q, q')}{1 + EnC_{i}} - K_{d} c_{i}$$
(b)
$$r_{i,j} = \frac{T_{ni} + T_{pj}}{T_{i,j}} (1 + |\Delta S_{o} - \Delta S_{exp}|)$$
(c)
$$\frac{\Delta c_{i}}{\Delta t} = K_{int} C_{i_{int}} + K_{ext} C_{i_{ext}}$$
(2)

of a negative feedback, the previously selected antibody ab_* will increase its affinity towards the other unselected antibodies $ab \in l$. Affinities are used for calculating the variation of concentration for the antibodies, as shown in equation 2(a). Affinity $r_{i,j}$ between generic antibodies iand j are calculated according to equation 2(b). The same mechanisms are also applied to the external network, as shown in the example situation depicted in Figure 4. The purpose of the external network is to share experiences throughout the creature: if, for instance, lymphnode l_{c_i} obtained a negative feedback, the reason for it could be ascribed to the neighbouring units that did not push/pulled in the right direction; vice-versa, if the same lymphnode obtained a positive feedback, the other neighbouring units should be aware of that, even if they experienced a negative The SelfEx algorithm should be able to find a balance between these situations.

Equation 2(b) is borrowed directly from Ishiguro et al. (1995) and forces selection of the same antibody in a subsequent similar situation (in the case of positive feedback) and vice-versa. T_{pj} corresponds to the total number of evaluation periods over which ab_j received positive feedback and T_{ni} are the total number of times ab_i received a penalty; $T_{i,j}$ is the number of times both antibodies i and j have been activated. In contrast to Ishiguro et al. (1995) we multiply the quantity representing the ratio of positive to negative feedback by a term proportional to the difference between obtained and expected distance travelled to represent functional utility.

Dynamics The *concentration* c_i of an antibody i determines its ability to compete against other antibodies to be able to execute its action and is dependent on its affinity with other antibodies. We apply an equation very similar to the differential equation suggested by Ishiguro et al. (1995) to modify concentration, given in equation 2(a). As visible in equation 2(a), we can identify four components and each component is controlled by a constant value. The first term represents *stimulation* of an antibody, the second term *suppression*, the third term the *stimulation* of the antibody from the environment (proportional by the distance between conditions and inversely proportional by the energy consumption measure), and the final term is a *decay* term represent-

ing the tendency of antibodies to die if not stimulated. In order to calculate the concentration of an antibody due to its *internal* network, $C_{i_{int}}$, the equation is applied over the N_i antibodies in the lymphnode of antibody i. The concentration of the i due its *external* network $C_{i_{ext}}$ is calculated by applying the equation over the N_e antibodies in its external network. Finally, its total concentration its calculated by weighting the contributions from the internal and external network as in (c) where K_{int} and K_{ext} are constants. The final value of concentration is then stabilized through a squashing function as defined in Ishiguro et al. (1995).

Meta-dynamics Meta-dynamic processes create new antibodies which can become integrated into the network. In contrast to previous meta-dynamic models (e.g. Ishiguro et al. (1995)), in our SelfEx model, the creation of new antibodies is not a continuous process but is triggered by stagnation in the network. Specifically, mutation is triggered whenever more than one antibody converges to the same concentration, a condition that (according to initial experiments) occurs when the creature becomes stuck over a prolonged period of time. The α mutation operator, triggered when two or more antibodies reach the same concentration level, creates a new antibody in which the condition field is set to the current unit orientation and all other fields are averaged among all the antibodies that share the same concentration value. To better understand what averaging the action field of an antibody means, we can consider an example situation in which two antibodies (i and j) share the same highest concentration value: let us suppose that the action during the positive phase of i is (0,0,-1) while in j is (0,1,0) then the new antibody k will feature an action during the positive phase of (0,0.5,-0.5). As a result, new antibodies enable the unit to move though composite directions, hence providing the single unit with the basis to create new movement patterns.

A second mutation operator refines new antibodies in order to generate new obstacle avoidance strategies. Mutation β occurs according to a probability P_{β} as described in equation 3. M is the current number of antibodies and it increases whenever an α mutation occurs, while N is the initial number of antibodies. K_a is a constant that regulates how often this kind of mutation can occur. As soon as M-N>0,

there is a non-zero probability that a new antibody will be created featuring the same condition and expected utility field as the last selected antibody. The action field is calculated by detecting the dominant direction of the last antibody and then inverting its direction. For example, if the positive phase of the last selected antibody i featured an action represented as (0.8,0.2,0), then the newly generated antibody k will feature an action in the positive phase represented as (-0.8,0,0). Once a β mutation occurs, N is set to M and all the affinity and concentration values are reset to their initial values.

$$P_{\beta} = \frac{M - N}{K_a} \tag{3}$$

Experiments and Results

After the pre-experimental phase, the same initial values of inter-antibodies affinities and concentrations are assigned to all the antibodies. The mechanism used in the experiment is shown in algorithm 1.

```

The algorithm is tested in an arena represented by a room that is confined between 4 walls. The algorithm is implemented in Javatm (jdk v. 1.7.0_45) using *JOGL* (http://jogamp.org/jogl/www/) for visualization purposes and *jinngine* as physics engine (Silcowitz-Hansen (2010)). After the pre-experimental phase (performed just once before the experiments), each unit in the creature is initialised with a population of 50 antibodies; each antibody is then set to the initial concentration $c_i = 0.5$. Parameters that were fixed during the experiments were $K_a = 3$, $K_d = 0.25$, $T_{eval} = 2s$ while all the other parameters undergo a process of search in order to find their best combinations resulting in settings of $K_p = 1$, $K_n = 0.85$, $K_D = 0.5$, $K_{int} = 0.45$

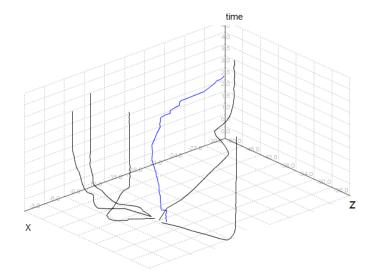

Figure 5: 50 time interval experiment in which all the trajectories caused by the pre-coded movement patterns (in black) are compared to SelfEx (in blue).

and $K_{ext} = 0.55$. Experiments are repeated 10 times with the total energy consumed and average distance covered (per single time interval) over varying time intervals; both these indicators are averaged throughout the whole creature. Experimental goals are to: (a) investigate whether pre-coded movement patterns can be combined in order to show different movement trajectories; (b) optimise distance travelled (c) optimise energy consumption.

Indicative results showing trajectories over a single run are depicted in Figure 5 and Figure 6. The y axis indicates movement over time, thus stationary behaviour is observed whenever there is no change in the XZ plane.

In Figure 5 shows that the evolved SelfEx trajectory differs from the single pre-coded movement patterns in that initially it makes slow progress, but once movement is established it continues throughout the experiment in a different trajectory.

In Figure 6 obstacle avoidance in addition to continuous movement is clear, as the plot shows how the creature manage to step back from walls.

In Figure 7 total energy consumption over time is shown, compared to the least costly single movement pattern (Type3) and the most costly (Type2, Type5). Over 10 runs, the average energy consumption is 10.11 (standard deviation $\sigma=0.128$), while the average distance covered per single time interval is $avg\Delta S=0.38$ ($\sigma=0.129$). The comparison with the 5 pre-coded movement patterns is shown in Table 2^2 . Our SelfEx algorithm was able to discover new trajectories by combining *pieces* of pre-coded move-

²Do note that the outcomes of the pre-coded patterns are deterministic.

Table 2: Average perfomance

ment patterns starting from the very first time interval of the experiment. This is an implication of the fact that each unit/lymphnode selects actions related to different movement patterns, thus creating new locomotion strategies even before starting generating new antibodies. The generation of new antibodies occurs whenever mixing the pre-coded strategies still does not cause movement to the creature; moreover the fitness function used during the sensing phase (equation 1(b)) and the third term of eq. 2 (a) forces the unit to constantly take into account its energy consumption, since the increment of the concentration value is inversely proportional to the energy cost of the movement: even if an antibody caused a positive feedback, the increase of the antibody concentration will not be substantial if the consumed energy is high; as an implication of this, less energy consuming actions are always selected.

Conclusions and future work

The paper has presented a modified version of an idiotypic network algorithm to evolve movement in a virtual creature. The algorithm was inspired by early work in robotic control by Ishiguro et al. (1995) and extends previous work in which a modified version of this algorithm was used to

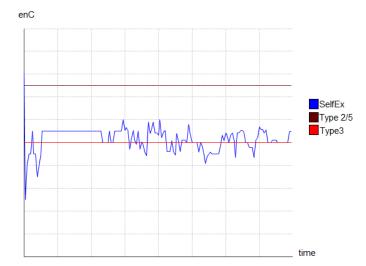

Figure 7: Energy consumption of SelfEx compared to Type1 (low energy), and Type3/Type5 (high energy).

select coordination patterns in swarm robotic applications (Capodieci et al. (2013b)). The presented control system is fully distributed, adaptive, and accounts for both functional and non-functional requirements. By only sharing a biological clock and by relying on a dual idiotypic network, the creature minimizes energy consumption and at the same time, discovers new movement trajectories and obstacles avoidance behaviours. Its novelty lies in the use of a 2-layer network, where antibodies interact in both internal and external networks, trading off unit-control against shared behaviours. Furthermore, the algorithm generates novel locomotion patterns in two ways: by combining fragments of existing patterns and by generating new patterns by mutating existing ones. As for future work, applying the same dual immune network for creating evolutionary morphologies for the creature is definitely an interesting development to be exploited in the near future.

Hold the Spot: Evolution of Generalized Station Keeping for an Aquatic Robot

Jared M. Moore and Anthony J. Clark

Michigan State University, East Lansing, MI, USA 48824 moore112@msu.edu

Abstract

In this paper, we present a strategy to evolve neurocontrollers in aquatic robots capable of generalized station keeping, that is, maintaining a position in the presence of various water flows. Evolved behaviors exhibit a variety of complex fin/flipper movements that enable the robot to react and move against changing flows. Moreover, results indicate that some sensor modalities are beneficial when the robot is placed in novel environments, though little used during the evolutionary process.

Introduction. Increasingly, aquatic robotic systems are being deployed to assist humans in challenging tasks (Tan et al., 2006). Although many systems rely on control from a human, autonomy allows robots to act independently in hostile or remote environments. Station keeping, also known as station holding, involves maintaining a position against external fluid flows, and is exhibited by many biological fish (Arnold, 1974). It is also of interest for aquatic robot sensor platforms that need to remain stationary while gathering data. In such cases, the autonomous control system needs to be able to respond to changing flows.

We previously examined the evolution of station keeping behaviors for individuals facing a single flow during their evaluation and evolutionary periods (Moore et al., 2013). Although successful in this task, individuals failed to maintain station when facing novel flows (i.e., flows that were not encountered during the evolutionary process). In this work, we focus on the evolution of *generalized* station keeping behaviors capable of handling multiple distinct flows. We investigate approaches to this problem through two separate experimental setups that utilize multiple flows during the evolutionary fitness evaluation. Evolved individuals are then evaluated in both previously seen and novel flows.

Results indicate that evolved individuals are able to hold station against flows encountered within and outside of the evolutionary process, exhibiting some generalized behaviors. Furthermore, additional sensor modalities increase an individual's ability to generalize to new flow conditions, even though they do not appear to be beneficial in environments encountered during evolution. This work provides an approach to developing a generalized control strategy for dynamic environmental conditions, and provides insight into the impact of sensory information for evolved neural controllers.

Methods. The simulated robot in this study emulates the form and function of a physical device, seen in Figure 1a. Pectoral flippers are capable of continuous 360° range of motion, while the caudal fin is limited to a $\pm 90^{\circ}$ symmetric range of motion. Sensory information includes inertial data (i.e., linear and angular acceleration at the robot's center of mass) and the previous update's motor commands. Information about the actual state of the motors is not used as most small continuous rotation servo motors do not provide this data. In two of the treatments, we include additional sensory information including the robot's pitch, roll, and yaw, along with the xyz flow information.

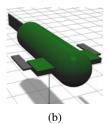

Figure 1: (a) Physical robot with 3D printed components. (b) Simulated agent derived from physical robot.

The Open Dynamics Engine (Smith, 2013), a 3D rigid-body physics library, is employed as the simulation environment. We extended ODE with a fluid dynamics model, discussed in (Moore et al., 2013), based on hydrodynamic drag adapted from (Wang et al., 2011) and (Sims, 1994). Neural controllers are evolved with the NEAT algorithm (Stanley and Miikkulainen, 2002). Individuals are evaluated based on their distance from the station point at 250ms intervals over a 60s evaluation period. The closer an individual is to the station point, the higher its fitness for that interval.

Experiments and Results. Videos of selected results are available at the following links:

```

Treatments 1 and 2 are conducted in an environment with a gradually changing side-to-side flow. At the start of an individual's evaluation, the flow originates from the front of the robot. The direction of the flow moves to one side, reaching its maximum angular offset of 63.4° at 15s. Halfway through the simulation (30s), the flow returns to the center, then moves to the opposite side with respect to the robot's initial orientation. A second environmental setup in Treatments 3 and 4 focus on holding station against a flow, then moving and stopping again at another flow. Five flows are possible: -45° , -22.5° , 0° , 22.5° , and 45° , of which two are randomly selected for an individual evaluation. Agents must be able to detect changes in the flow, or lack thereof. A total of nine possible flow combinations are possible during evolution.

Evolutionary results indicate that Treatment 1 (lacking additional sensors) slightly outperforms Treatment 2 during evolution. In Treatments 3 and 4, a reduced sensory capacity also leads to higher fitnesses in environments seen during the evolutionary process. However, in all treatments, evolved agents are able to maintain station effectively in the evolutionary environments.

The focus of this study, the evolution of generalized behavior, assesses individuals based on how they perform in novel flow conditions. Contrary to the evolutionary results, individuals evolved with additional sensory input achieve the best station keeping in novel environments. We hypothesize that the additional sensory information may be extra noise for an evolved ANN in a familiar environment (i.e. one seen during the evolutionary process), but is important information when encountering environments not previously seen.

We test evolved individuals in an environment containing both a change in direction and magnitude of the flow. Here, the flow begins at twice the magnitude encountered during evolution and is strong enough that individuals are physically unable to generate enough thrust to hold station. The flow is reduced after the first 20s of a 60s simulation, allowing agents to swim back towards the station point. Two individuals from Treatment 1 and 4 are shown in Video 5 with an individual from Treatment 4 depicted in Figure 2. Here, sensors are again beneficial in novel environments as the best performing individuals come from Treatment 4, which has the additional sensory information. Behaviors exhibited in this test indicate that these individuals are not evolved to swim against the flows at a steady rate, but can return to station when displaced by stronger, previously unseen flows.

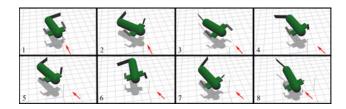

Figure 2: An evolved individual from Treatment 4 exhibits station keeping behavior by swimming back towards the origin after initially being pushed away from the station by a strong flow.

Discussion Unlike previous work (Moore et al., 2013), these treatments were effective in eliciting generalized station keeping. Surprisingly, the additional sensory information does not appear to increase the ability of individuals to hold station in environments encountered during the evolutionary process. However, when placed in previously unseen environments, individuals with extra sensory information are more effective than those relying on a limited set of sensors. This suggests that additional sensory information can be beneficial in unforeseen conditions. Future work includes determining why the additional information is beneficial, and pursuing the evolution of generalized controllers for different tasks.

Abstract

Neural plasticity and in particular Hebbian learning play an important role in many research areas related to artficial life. By allowing artificial neural networks (ANNs) to adjust their weights in real time, Hebbian ANNs can adapt over their lifetime. However, even as researchers improve and extend Hebbian learning, a fundamental limitation of such systems is that they learn correlations between preexisting static features and network outputs. A Hebbian ANN could in principle achieve significantly more if it could accumulate new features over its lifetime from which to learn correlations. Interestingly, autoencoders, which have recently gained prominence in deep learning, are themselves in effect a kind of feature accumulator that extract meaningful features from their inputs. The insight in this paper is that if an autoencoder is connected to a Hebbian learning layer, then the resulting Realtime Autoencoder-Augmented Hebbian Network (RAAHN) can actually learn new features (with the autoencoder) while simultaneously learning control policies from those new features (with the Hebbian layer) in real time as an agent experiences its environment. In this paper, the RAAHN is shown in a simulated robot maze navigation experiment to enable a controller to learn the perfect navigation strategy significantly more often than several Hebbian-based variant approaches that lack the autoencoder. In the long run, this approach opens up the intriguing possibility of real-time deep learning for control.

Introduction

As a medium for adaptation and learning, neural plasticity has long captivated artificial life and related fields (Baxter, 1992; Floreano and Urzelai, 2000; Niv et al., 2002; Soltoggio et al., 2008, 2007; Soltoggio and Jones, 2009; Soltoggio and Stanley, 2012; Risi and Stanley, 2010; Risi et al., 2011; Risi and Stanley, 2012; Stanley et al., 2003; Coleman and Blair, 2012). Much of this body of research focuses on Hebbian-inspired rules that change the weights of connections in proportion to the correlation of source and target neuron activations (Hebb, 1949). The simplicity of such Hebbian-inspired rules makes them easy and straightforward to integrate into larger systems and experiments, such as investigations into the evolution of plastic neural networks (Floreano and Urzelai, 2000; Soltoggio et al., 2008; Risi et al., 2011). Thus they have enabled inquiry into such diverse problems as task switching

(Floreano and Urzelai, 2000), neuromodulation (Soltoggio et al., 2008), the evolution of memory (Risi et al., 2011), and reward-mediated learning (Soltoggio and Stanley, 2012).

However, while Hebbian rules naturally facilitate learning correlations between actions and static features of the world, their application in particular to control tasks that require learning *new features* in real time is more complicated. While some models in neural computation in fact do enable low-level feature learning by placing Hebbian neurons in large topographic maps with lateral inhibition (Bednar and Miikkulainen, 2003), such low-level cortical models generally require prohibitive computational resources to integrate into real-time control tasks or especially into evolutionary experiments that require evaluating numerous separate individuals. Thus there is a need for a convenient and reliable feature generator that can accumulate features from which Hebbian neurons combined with neuromodulation (Soltoggio et al., 2008) can learn behaviors in real time.

Interestingly, such a feature-generating system already exists and in fact has become quite popular through the rise of deep learning (Bengio et al., 2007; Hinton et al., 2006; Le et al., 2012; Marc' Aurelio et al., 2007): the autoencoder (Hinton and Zemel, 1994; Bourlard and Kamp, 1988). Autoencoders, which can be trained through a variety of algorithms from Restricted Boltzmann Machines (RBMs) (Hinton et al., 2006) to more conventional stochastic gradient descent (Le et al., 2012) (e.g. similar to backpropagation; Rumelhart et al. 1986), aim simply to output the same pattern as they input. By training them to mimic their inputs, they are forced to learn key features in their hidden layer that efficiently encode such inputs. In this way, they accumulate such key features as they are exposed to more inputs. However, in deep learning autoencoders are usually trained for classification tasks through an unsupervised pre-training phase and in fact recent results have raised doubts on their necessity for such tasks anyway (Cireşan et al., 2012). The idea in this paper is that in fact autoencoders can instead be put to good use as feature accumulators that work synergistically with neuromodulated Hebbian connections that learn from the accumulating features in real time, as an autonomous

agent acts in the world. The resulting structure is the *Real-time Autoencoder-Augmented Hebbian Network* (RAAHN), a novel algorithm for learning control policies through rewards and penalties in real time.

In short, the key idea behind the RAAHN is that a missing ingredient that can reinvigorate the field of Hebbian learning is the ability of an autonomous agent to learn new features as it experiences the world. Those new features are then simultaneously the inputs to a neuromodulated Hebbian layer that learns to control the agent based on the accumulating features. In effect, the RAAHN realizes the philosophy that real-time reward-modulated learning cannot achieve its full potential unless the agent is simultaneously and continually learning to reinterpret and re-categorize its world. Introducing the RAAHN thereby creates the opportunity to build and study such systems concretely.

The experiment in this paper is intended as a proof of concept designed to demonstrate that it is indeed possible to learn autoencoded (and hence unsupervised) features at the same time as Hebbian connections are dynamically adapting based both on correlations with the improving feature set and neuromodulatory reward signals. In the experiment, simulated robots with two kinds of sensors (one to see the walls and the other to see a non-uniform distribution of "crumbs" on the floor) are guided through a maze to show them the optimal path, after which they are released to navigate on their own. However, supervised learning does not take place in the conventional sense during this guided period. Instead, both the autoencoder and the Hebbian connections are adjusting in real time without supervisory feedback to the autoencoder. Furthermore, to isolate the advantage of the autoencoder, two other variants are attempted - in one the Hebbian connections learn instead from the raw inputs and in the other the Hebbian connections learn from a set of random features (e.g. somewhat like an extreme learning machine; Huang and Wang 2011).

The main result is that only the full RAAHN learns the optimal path through the maze in more than a trivial percentage of runs, showing not only that it is possible to train an autoencoder and Hebbian connections simultaneously, but that in fact the autoencoder component can be essential for incorporating the most important features of the world.

While the RAAHN could be viewed in the context of reinforcement learning (RL), it is important to note that the approach is rather aimed at issues outside typical RL. In particular, the RAAHN can be viewed as a platform for later integrating more advanced and realistic Hebbian learning regimes, e.g. with distal rewards (Soltoggio et al., 2013) to demonstrate more convincingly their full potential.

In effect, the RAAHN is a new way to think about plasticity that goes beyond the proof of concept in this paper. It is among the first methods to suggest the potential for *realtime deep learning for control*. In that way it opens up a large and rich research area for which this paper represents

an initial step. If Hebbian connections can be trained from a dynamically adjusting autoencoder, then perhaps one day they will learn in real time from deepening stacked autoencoders or within complex evolved networks that incorporate autoencoders as a basic element. While much remains to be explored, the initial study here thereby hints at what might be possible in the future.

Background

This section reviews Hebbian learning in artificial neural networks (ANNs) and the application of autoencoders in deep learning.

Hebbian ANNs

The plain Hebbian plasticity rule is among the simplest for training ANNs:

$$\Delta w_i = \eta x_i y,\tag{1}$$

where w_i is the weight of the connection between two neurons with activation levels x_i and y, and η is the learning rate. As an entirely local learning rule, it is appealing both for its simplicity and biological plausibility. For this reason, many researchers have sought to uncover the full extent of functionality attainable by ANNs only of Hebbian rules.

As researchers have gained insight into such networks, they have also found ways to increase the rule's sophistication by elaborating on its central theme of strengthening through correlated firing (e.g. Oja 1982; Bienenstock et al. 1982). Researchers also began to evolve such ANNs in the hope of achieving more brain-like functionalities by producing networks that change over their lifetime (Floreano and Urzelai, 2000; Niv et al., 2002; Risi and Stanley, 2010; Risi et al., 2011; Stanley et al., 2003).

One especially important ingredient for Hebbian ANNs is neuromodulation, which in effect allows Hebbian connections to respond to rewards and penalties. Neuromodulation enables the increase, decrease, or reversal of Hebbian plasticity according to feedback from the environment. Models augmented with neuromodulation have been shown to implement a variety of typical features of animal operant learning such as reinforcement of rewarding actions, extinction of unproductive actions, and behavior reversal (Soltoggio and Stanley, 2012; Soltoggio et al., 2013). The combination of Hebbian ANNs with neuromodulatory signals in recent years has especially inspired neuroevolution and artificial life researchers by opening up the possibility of evolving ANNs that can learn from a sequence of rewards over their lifetime (Soltoggio et al., 2008, 2007; Soltoggio and Jones, 2009; Soltoggio and Stanley, 2012; Risi and Stanley, 2012; Coleman and Blair, 2012).

However, one limitation of these cited studies is that the inputs are generally heavily pre-processed to provide meaningful and useful feature to the neural substrate that performs Hebbian plasticity. A natural question is whether such useful features can in principle emerge in real-time during the

agent's lifetime, and in combination with the associative, reward-driven learning provided by Hebbian plasticity. As this paper argues, the autoencoder, reviewed next, is an appealing candidate for playing such a role.

Autoencoders in Deep Learning

The idea behind the autoencoder is to train a network with at least one hidden layer to reconstruct its inputs. The auto encoder can be described as a function f that encodes a feature vector x (i.e. the inputs) as a set of hidden features h = f(x). A second function q then decodes the hidden features h (typically a hidden layer within an ANN) into a reconstruction r = g(h) (Bengio et al., 2013). The hope of course is that once trained, r will be as close as possible to x for any input x. While many possible autoencoder models exist, the parameters of the autoencoder (which can be represented as weights in an ANN) are often the same for the encoder and decoder, which means in effect that the weights are bidirectional (Bengio et al., 2013). The main property of the autoencoder that makes it interesting is that by forcing it to learn hidden features h that can reconstruct input instances, under the right circumstances the features of h are forced to encode key features of the input domain. For example, edge detectors might arise in h for encoding images (Hinton et al., 2006).

Autoencoders began to gain in popularity considerably after researchers observed that they can help to train deep networks (i.e. ANNs of many hidden layers) through a pretraining phase in which a stack of autoencoders is trained in sequence, each one from the previous (Bengio et al., 2007; Hinton et al., 2006; Le et al., 2012; Marc'Aurelio et al., 2007), leading to a hierarchy of increasingly high-level features. Because it was thought that backpropagation struggles to train networks of many layers directly, pre-training a stack of such autoencoders and then later completing training through e.g. backpropagation was seen as an important solution to training deep networks. Although later results have suggested that in fact such pre-training is not always needed (Cireşan et al., 2010) (especially in the presence of an abundance of labeled data), it remains a compelling demonstration of unsupervised feature accumulation and remains important for training in the absence of ample labeled data (Bengio et al., 2013). In any case, typically the main application of such deep networks is in classification problems like handwriting recognition.

Another appeal of autoencoders is that there are many ways to train them and many tricks to encourage them to produce meaningful features (Ranzato et al., 2006; Le et al., 2012). While RBMs (a kind of probabilistic model) can play a similar role to autoencoders, classic autoencoders in deep learning are generally trained through some form of stochastic gradient descent (Le et al., 2012; Bengio et al., 2007) (like backpropagation), as is the case in this paper. However, the important issue in the present investigation

is not the particular details of the autoencoder; in fact an advantage of the RAAHN formulation is that any autoencoder can be plugged into the RAAHN. Thus as autoencoders are refined and improved, RAAHNs naturally benefit from such improvements and refinements. It is also possible that the real-time context of RAAHNs will provoke more attention in the future to identifying autoencoder formulations most suited to real time.

Approach: Real-time Autoencoder-Augmented Hebbian Network

The Real-time Autoencoder-Augmented Hebbian Network (RAAHN) approach introduced in this paper consists of two distinct components: the autoencoder and the Hebbian learner. The simplest implementation consists of an ANN with a single hidden layer; connections from the inputs to the hidden layer are trained as an autoencoder and connections from the hidden layer to the outputs are trained with a Hebbian rule. Thus the hidden layer represents a set of features extracted from the inputs that a Hebbian rule learns to correlate to the outputs to form an effective control policy.

Both of these components can be implemented in a number of different ways. The particular implementation described in this section, which is tested later in the experiment, serves as a proof of concept. It is designed accordingly to be as simple as possible.

Autoencoder Component

The autoencoder in this experiment is a heuristic approximation of the conventional autoencoder (Bengio et al., 2013) that was chosen for simplicity and ease of implementation. It is important to note that it suffices for the purpose of this experiment because it converges to within 5% of the optimal reconstruction in every run of the experiment in this paper. This consistent convergence validates that the simplified autoencoder effectively approximates the behavior of an ideal autoencoder without loss of generality. Of course, more sophisticated autoencoder implementations can fill the same role in future implementations of the RAAHN.

The simplified autoencoder component consists of a single layer of bidirectional weights that are trained to match the output of the backwards activation with the input to the forward activation. On each activation of the network, first the inputs I feed into the the regular forward activation of the hidden layer H (the input layer is fully connected to the hidden layer) in the following manner. For each hidden neuron j, forward activation A_j is calculated:

$$A_j = \sigma \left(\sum_{i \in I} (A_i \cdot w_{i,j}) + b_j \right), \tag{2}$$

where σ is a sigmoid function, A_i is the value of input neuron $i \in I$, $w_{i,j}$ is the weight of the connection between neurons i and j, and b_j is the bias on hidden neuron j. Next, the

forward activation values for hidden layer H are used to calculate the *backwards activation* to input layer I. For each input neuron i, backward activation B_i is calculated:

$$B_i = \sigma \left(\sum_{j \in H} (A_j \cdot w_{i,j}) + b_i \right), \tag{3}$$

where σ is the same sigmoid activation function as in equation 2, A_j is the forward activation on hidden neuron $j \in H$, and b_i is the bias on input neuron i.

After backwards activation is calculated, for each input neuron i, an error E_i is calculated:

$$E_i = A_i - B_i. (4)$$

Finally, as a simple heuristic for reducing reconstruction error (modeled after the perceptron learning rule), each weight is adjusted according to

$$\Delta w_{i,j} = \alpha E_i A_j,\tag{5}$$

where α is the learning rate (which is set to a small value to prevent convergence before an adequate number of input samples have been seen). This autoencoder was validated on data from the experiment to ensure that it converges with very low error (less than 5% from the optimal reconstruction). It is important again to note that any autoencoder could substitute for this simple model, whose particular mechanics are not essential to the overall RAAHN.

The experiment in this paper applies the proposed RAAHN system to a simulated robot control task. On each simulated time tick, the agent perceives values on its sensors and experiences a network activation. Thus, each time tick constitutes one training sample for the purpose of training the autoencoder connections. In this paper, a batch-style training system is implemented in which training samples are added to a history buffer of size n and autoencoder training is applied several times on the entire history buffer every $\frac{n}{2}$ ticks. Batch-style training is selected because many popular autoencoder training methods such as L-BFGS require batch training, although in preliminary experiments the system was found to perform well with both large and small values of n.

Hebbian Component

In the RAAHN system, connections between learned features and the outputs are trained with a modulated Hebbian learning rule, which is similar to the simple Hebbian rule (equation 1) with an added term to allow for the influence of reward and penalty signals. In this way, connections are only strengthened when a reward signal is received and when a penalty signal is received, the rule switches to anti-Hebbian (which serves to weaken connections). The modulated Hebbian rule is

$$\Delta w_i = m\eta x_i y,\tag{6}$$

where m is the modulation associated with the training sample. The Hebbian rule without modulation is like assuming that all training samples are positive; modulation allows training samples to be marked with varying degrees of positive or negative signal, which is a more flexible learning regime. The details of the modulation scheme have a significant impact on the effectiveness of learning. In the maze-navigating experiment in this paper, a simple modulation scheme is selected in which modulation is positive when the robot turns away from a wall, negative when the robot turns towards a wall, and neutral (m=0, corresponding to no learning) when there is no change. Specifically, the modulation component in this paper is calculated as the difference between the front-pointing rangefinder sensor activation on the previous tick and on the current tick, normalized to the range -1 to 1.

Modulated Hebbian learning following equation 6 is applied to every connection of the Hebbian component of the RAAHN system on each tick. The system in essence learns correlations between the developing feature set discovered by the autoencoder component and an output pattern required for effective control. The Hebbian rule is useful as a learning mechanism to connect autoencoder features to outputs because it is invariant to starting conditions. Thus, if the pattern of features in the learned feature set changes for some reason (e.g. the nature of the task environment shifts significantly), the Hebbian component can simply learn new correlations for the new feature set, enabling calibration in real-time as the feature set itself is refined.

Experiment

To demonstrate the effectiveness of the proposed RAAHN system, a maze-navigating control task is introduced in which a robot agent must make as many laps around the track as possible in the allotted time. The challenges of the task are two-fold. The first and more trivial challenge is for the controller to avoid crashing into walls, which would prevent it from completing any laps at all (robots that crash into walls almost always remain stuck on the wall, preventing any further movement). The second challenge arises because there are multiple round-trip paths around the track (figure 1). In particular, the track consists of an optimal path with two attached "detours" - longer routes that lead the robot off the optimal path before re-joining it. There is one detour attached to the inner wall of the track as well as one detour attached to the outer wall of the track. Both detours take significantly longer to traverse than the optimal path; thus taking either detour (or both detours) reduces the amount of laps the robot can make in the allotted time.

Robots in this task have access to two different types of sensors (figure 2). First, robots are equipped with a set of 11 wall-sensing rangefinders, each 200 units in length (slightly longer than the narrowest portions of the track) and equally spaced across the frontal 180 degrees of the robot (with one rangefinder pointing directly towards the front). Notice also

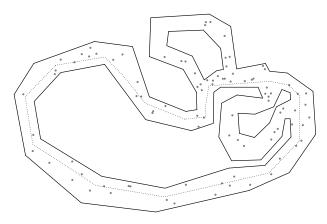

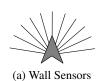

Figure 1: **Multiple path environment.** Robots navigate this cyclical track that consists of an optimal path (in terms of the shortest lap time) with two attached suboptimal detours. The training phase autopilot is denoted by a dotted line. Crumbs (gray dots) are scattered non-uniformly around the track to enable the identification of unique locations.

in figure 1 that there are "crumbs" scattered nonuniformly across the track. The random distribution of these crumbs means the robot can in principle identify unique locations. For this purpose, robots are equipped with 33 crumb-density sensors that sense the density of crumbs within a rangelimited pie slice. The crumb-density sensors are divided into three sets of 11 (near, mid, and far), each set equally spaced across the frontal 180 degrees of the robot. Near-type crumb density sensors sense crumbs between 0 and 132 units in distance, mid-type between 133 and 268 units, and far-type between 269 and 400 units. If one crumb is present within a crumb density sensor's area, then the sensor experiences 0.33 activation; it experiences 0.67 activation for two crumbs and 1.0 activation for three or more crumbs (it is rare for more than three crumbs to be present in a sensor's area). Robots have a single effector output, corresponding to the ability to turn right or left. Otherwise, robots are always moving forward at a constant velocity (5 units per tick).

In the experiment, robots first experience a *training phase*. During this phase an autopilot drives the robot around the track for 30,000 ticks. The robot is shown a path that never deviates onto suboptimal detours. However, the driving within the chosen path is not perfect. The autopilot, whose path (shown in figure 1) is deterministic, does not crash but it also does not always drive in the precise middle of the road; that way it is exposed to the penalty for moving too close to walls. During this training phase the autopilot overrides the robot's outputs, forcing it to move along the autopilot's route, while both the autoencoder and Hebbian learning are turned on. After the training phase, autopilot is turned off, learning is stopped, and agents are released to follow their learned controller for 10,000 ticks (the evaluation phase).

It is important to note that while this experiment could

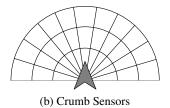

Figure 2: **Agent sensor types.** Robots have a set of 11 rangefinder sensors (a) for detecting the presence of walls (up to a maximum distance of 200 units). Robots also have an array of 33 non-overlapping range-limited pie slice sensors (b) to sense crumbs in the environment. Each sensor can detect up to three crumbs with increasing levels of activation, at which point sensor activation is capped. These crumb sensors form a semicircular grid up to a distance of 400 units across the frontal 180 degrees of the robot.

have been performed with a supervised learning framework, RAAHN is not restricted to supervised learning. Because RAAHN organizes its feature set and learns a control policy in real-time as it accumulates information about its environment, it can in principle perform when there is no autopilot training phase and robots are simply released into the world under their own control from the first tick. However, this type of application of RAAHN would require a more advanced modulation scheme that also rewards making laps and perhaps would require confronting the distal reward problem. In the interest of introducing the core learning mechanism without other potentially confusing variables, such a study is reserved for future investigation. It is also critical to note that the experiment even as devised is not supervised learning because the autoencoder is accumulating features in real-time with no error feedback whatsoever, just as would happen if the agent were allowed to control its own movements while learning. The autopilot simply ensures that the experience of the robot is consistent in this initial study so we can understand what is typically learned by a RAAHN when experience is consistent (though of course from different initial random starting weights).

Preliminary experiments revealed that a robot controller consisting of only rangefinder sensors connected directly to the output with Hebbian connections (i.e. without an autoencoder) was able to navigate the track with a trivial wallfollowing behavior that keeps close to and parallel to a wall on either the right or the left side while moving forward around the track. Because there is a detour attached to both the inner wall and the outer wall, robots performing such a trivial wall-following behavior will inevitably take one of the two detours each lap. The optimal behavior, which involves *avoiding* both detours while moving around the track at maximum speed and avoiding crashing into walls, therefore requires extra information and neural structure than

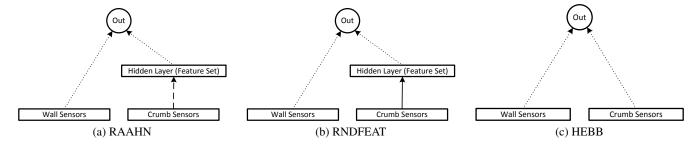

Figure 3: **Variant network structures.** Three variant networks are compared in the main experiment. Individual neurons within sensor array layers and hidden layers have been omitted for clarity. Layers shown as connected are fully connected. Dotted lines represent connections trained with modulated Hebbian plasticity. Dashed lines represent connections trained as an autoencoder. Solid lines represent static (non-trained) connections.

Hebbian learning from the raw rangefinder information. For the purposes of the main experiment, the crumb sensors and a layer of features extracted from the crumb sensors serve as this extra information. With the crumb sensors, robots in principle have the ability to distinguish between different parts of the track that have different "density signatures" (e.g. the opening for the outer detour causes a very different activation pattern on the crumb sensors than the opening for the inner detour). This distinguishing information makes it possible to enact different policies at different parts of the track (e.g. switching to following walls on the left side rather than the right side after passing the outer detour going around the track clockwise), which is essential for avoiding both detours and proceeding around the track along the optimal path. Thus an optimal agent must somehow encode these higher-level features.

The main experiment consists of a comparison between three very different learning regimes: RAAHN, RNDFEAT (random features), and HEBB. These methods differ only in the way that they process the extra information from the crumb sensors; all three methods include direct Hebbian connections from the wall-sensing rangefinders to the output. **RAAHN** (figure 3a) includes an autoencoder-trained feature set of 7 neurons drawn from the 33 crumb sensors. This feature set then feeds into the output via Hebbian connections. **RNDFEAT** (figure 3b) has the same structure as RAAHN, except autoencoder training is turned off. This configuration means that RNDFEAT has a set of 7 static random features. Results for RNDFEAT with 30 and 100 random features are also included (as RNDFEAT30 and RNDFEAT100, respectively), which resemble the idea behind extreme learning machines (Huang and Wang, 2011). Finally, **HEBB** (figure 3c) consists of all inputs directly connected to the output via Hebbian connections. In all variants, connection weights are randomly initialized with a uniform distribution of small magnitude (with average magnitude equal to 5% of the maximum weight of 3.0); increasing the magnitude of initial weights in preliminary experiments did not significantly impact the results.

Experimental Parameters

Batch autoencoder training occurs every 800 ticks on a history buffer of training samples spanning the past 1,600 ticks, which is roughly equivalent to the amount of time required to make a full lap during the training phase (recall that training encompasses 30,000 total ticks). The learning rate α for autoencoder training is 0.001. Each time batch training occurs, the buffer of training samples is spun through 10 times, with backwards activations recalculated after each pass. The result is that the autoencoder mostly converges by the end of a single training pass (autoencoder error is reduced to less than 5% of the optimal reconstruction). The Hebbian learning rate η for all variants is 0.2. These parameter settings were found to be robust to moderate variation through preliminary experimentation.

Results

In the results reported in this section, performance is based on the kinds of paths followed over the 10,000 tick evaluation period, averaged across 1,000 trials. Learned behaviors were found to be consistent, that is, the behavior observed during the first lap is very similar to the behavior on all other laps, especially with respect to which detours are taken (if any). Therefore, it is possible to place behaviors that navigate the maze into two key categories: First are robots that follow the optimal path; these best-performing robots never take a detour and thereby stay on the best path. Second are wallavoiding robots who deviate from the optimal path by taking at least one detour but still effectively avoid crashing and thereby make several clean laps around the track. Learned behaviors that do not fall into either of these two categories do not complete the course because they crash into walls. Experimental results are reported in figure 4 as the percentage of robots trained with each scheme that fall into either

The main result is that the RAAHN learns the optimal path four times more often than the closest variant (RNDFEAT30). HEBB never learns the optimal path. However, the results

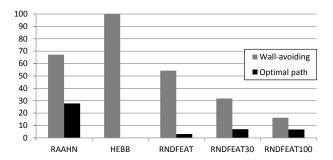

Figure 4: **Percentage of wall-avoiding and optimal path followers.** Results for each variant are percentages calculated over 1 000 evaluations.

confirm that pure Hebbian learning (HEBB) is invariant to starting conditions – it performs exactly the same in each of 1,000 trials (each with different initial weights). HEBB robots always follow the inner detour. Both RAAHN and RNDFEAT variants experience some failed trials, though RAAHN experiences the least. These failures come in many forms: robots that get stuck on sharp corners when exiting a detour are a common observed failure. Some robots fail immediately after leaving autopilot by spinning in tight circles – this type of failure (immediate failure) is not consistent across all methods. Interestingly, immediate failure occurs in 1.7% of RAAHN runs, 15.3% of RNDFEAT runs, 33.4% of RNDFEAT30 runs, and 58.6% of RNDFEAT100 runs.

Discussion and Future Work

The HEBB variant, which attempts to incorporate the crumb sensor inputs directly as a static feature set, never achieves optimal behavior. Thus, raw crumb sensor information appears to be insufficient for Hebbian learning to discover optimal behaviors on this task, suggesting the necessity of higher-level features. While HEBB's performance could in principle be manipulated by manually changing the set of static features (e.g. preprocessing the inputs), doing so is like the human playing the role of the RAAHN. This paper focuses instead on the automated generation of features with the intent of building a learning system that is generally applicable to future domains that may be too complicated for manual preprocessing of features or where adaptation of the feature set is required (e.g. large, open-ended artificial life worlds).

One naive way to automatically generate higher level features is through a hidden layer with random incoming weights, such as in RNDFEAT. While such random features bring optimal behaviors in this task into the realm of possibility, they do not constitute a strong method for achieving such behaviors – even the best RNDFEAT-type variant (RND-FEAT30) achieves the optimal behavior only 7% of the time. Adding more random features (as in RNDFEAT100) only causes performance to deteriorate. Indeed, the rate of immediate failures increases sharply as more random features are added to the feature set (compared to 7 features in RND-

FEAT), which suggests that additional random features are destructive as they wash out the useful signal from the wall sensors (e.g. leading to many immediate failures).

RAAHN does not suffer from the pathology of immediate failures because training the feature set as an autoencoder encourages the discovery of a more balanced feature set. RAAHN also discovers optimal behaviors four times as often (28%) as the best RNDFEAT-type variant (RND-FEAT30), which demonstrates the autoencoder's ability to learn useful information about the environment. Furthermore, RAAHN's feature set is dynamic, enabling it in principle to adapt to changing environmental conditions, while RND-FEAT's feature set cannot. Future RAAHNs might even add new layers over time, vielding a kind of real-time deep learning for control. A deeper analysis of neural activity within the autoencoder layer as well as experiments with larger quantities of autoencoded features will indicate the extent of the RAAHN's potential to be expanded in real-time in this way. Furthermore, as the state of the art in Hebbian learning advances, such as by addressing distal rewards (Soltoggio and Steil, 2013), the RAAHN benefits from the advancing capabilities as well.

Finally, while 28% optimality still may appear to leave room for improvement, it is important to note that it is actually impressive for the simple training regimen in this experiment. In particular, during training, robots were never actually shown the detours that they are expected to avoid, so there can be little to no representation of the inside of detours within the autoencoder. Furthermore, robots were not explicitly rewarded for taking the optimal path or penalized for taking detours. Rather, the reward scheme only rewards steering away from walls. Thus optimal paths were acquired entirely implicitly through observing the path taken by the autopilot and encoding its key features, suggesting the power of the RAAHN to derive behaviors from such features based on sparse and indirect feedback. In the future, when RAAHN-controlled networks are released to explore completely on their own while rewards are experienced, they have the potential to acquire a significantly wider breadth of abilities.

Conclusion

The experiment in this paper showed that a Hebbian layer can learn during ongoing behavior in real time from an autoencoder placed below it under controlled conditions. The implication of this initial step is that the RAAHN is a synergistic union that opens up many opportunities for new investigations. For example, what is possible to achieve when the RAAHN is allowed to acquire new features while exploring on its own without an autopilot? Can increasingly complex skills be acquired if the depth of the autoencoder is allowed to expand during learning? Can ANNs be evolved to incorporate both autoencoders and Hebbian plasticity? These are among the intriguing possibilities created by the RAAHN.

This paper introduces JBotEvolver, a versatile simulation platform for research and education in evolutionary robotics (ER). JBotEvolver is a Java-based open-source, cross-platform framework available at https://code.google.com/p/jbotevolver/ under the GNU GPL. JBotEvolver has been used in a number of previous ER studies of our research group, from offline evolution to online evolution and learning, and from single to multirobot systems (for examples see Duarte et al. (2014a,b); Silva et al. (2012a,b)), and in a number of undergraduate and graduate courses at ISCTE-IUL.

JBotEvolver's main features are its ease of installation and use, and its versatility in terms of customization and extension. A fundamental design philosophy behind JBotEvolver is to provide a basis for ER experiments without the need for detailed framework-specific knowledge. Following this philosophy, JBotEvolver enables the configuration of experiments programmatically or via a plaintext file that specifies which features will be included in the simulation. The corresponding classes are then seamlessly loaded in execution time via Java's Reflection API. In this way, JBotEvolver can also make use of external, user-defined classes that extend the base implementation. Additionally, JBotEvolver is selfcontained, but can also be used as an external library in other applications. One example is the automation system that allowed us to evolve hierarchical controllers by automatically combining controllers from independent evolutionary setups (Duarte et al., 2014a).

The user can extend the main components of JBotE-volver such as the environments in which the robots operate, the physical objects of the environment, the robot models, the evaluation functions, the evolutionary algorithms, and the type and structure of the controllers. For instance, while our studies have focused on the evolution of neural network-based controllers (Duarte et al., 2014b,a; Silva et al., 2012a,b), JBotEvolver does not preclude other approaches such as genetic programming or evolutionary fuzzy systems. JBotEvolver features a 2D differential-drive kinematics engine that has been used to simulate multirobot systems with up to thousands of robots (Duarte et al.,

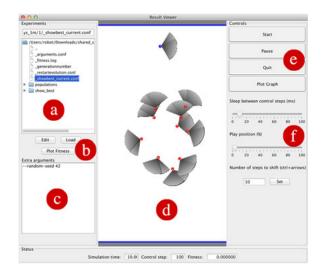

Figure 1: Result Viewer GUI: (a) file tree for navigating experimental results, (b) options to load or edit files, and to plot the fitness of controllers, (c) text area for overriding experimental arguments, (d) basic 2D visual renderer, (e) options to start/stop the experiments, quit the simulator, and plot neural network activity, and (f) sliders to change the speed of the simulation and to fast-forward/rewind.

2014b). The 2D engine can also be extended or replaced by user-defined engines with different dynamics. With respect to the experimental setup, JBotEvolver allows the user to control the degree of realism of the simulations by allowing, for instance, the use of sensors modelled based on samples from real robots (Duarte et al., 2014a) and the configuration of the robots' control cycle frequency. In terms of robots, JBotEvolver includes a model of the e-puck robot and allows for fully customizable 2D robot models.

An important characteristic of JBotEvolver is that controller evaluations are defined as tasks that can be executed sequentially or in parallel on a workstation. We have also included a connector for Conillon (Silva et al., 2011), a lightweight platform for distributed computing that enables a significantly speed-up of evolutionary processes through

parallelization. We have used Conillon to distribute JBotE-volver tasks to over 400 cores. Conillon's dynamic request of Java classes allows tasks with different codebases to be submitted. Worker nodes can be added to the computing network in an ad-hoc manner either through: (i) a standalone application, (ii) a Java applet running in a browser, or (iii) as a screensaver on PCs. In addition, the Encog framework¹ implementation of the neuroevolutionary NEAT algorithm (Stanley and Miikkulainen, 2002) has been interfaced with JBotEvolver.

A number of alternative simulators for evolutionary robotics are available, including: (i) Simbad (Hugues and Bredeche, 2006), (ii) Webots (Michel, 2004), (iii) AR-GoS (Pinciroli et al., 2012), (iv) Enki², and (v) the Player Project (Gerkey et al., 2003), which includes the 2D simulator Stage and the 3D simulator Gazebo. In comparison with such platforms, as described in Table 1, the key advantages of JBotEvolver are its extensibility, ease of use, and versatility. JBotEvolver has a number of expert-oriented features, such as the mechanisms for the distributed execution of experiments, and non-expert-oriented features. From the GUI (Fig. 1), it is, for instance, possible to navigate between results of different evolutionary runs or setups, analyze fitness score plots, visualize the controllers' input and output values, stop and resume experiments, and modify experimental configurations on-the-fly.

To summarize, JBotEvolver is a versatile, easy to deploy and operate simulation platform intended for both expert and non-expert users. In our ongoing work, we continue to use JBotEvolver, and we are extending it to support different robot models and types of robots, including aquatic drones.

Abstract

Evolutionary techniques driven by behavioural diversity, such as novelty search, have shown significant potential in evolutionary robotics. These techniques rely on priorly specified behaviour characterisations to estimate the similarity between individuals. Characterisations are typically defined in an ad hoc manner based on the experimenter's intuition and knowledge about the task. Alternatively, generic characterisations based on the sensor-effector values of the agents are used. In this paper, we propose a novel approach that allows for systematic derivation of behaviour characterisations for evolutionary robotics, based on a formal description of the agents and their environment. Systematically derived behaviour characterisations (SDBCs) go beyond generic characterisations in that they can contain task-specific features related to the internal state of the agents, environmental features, and relations between them. We evaluate SDBCs with novelty search in three simulated collective robotics tasks. Our results show that SDBCs yield a performance comparable to the task-specific characterisations, in terms of both solution quality and behaviour space exploration.

Introduction

Evolutionary robotics (ER) is focused on the application of evolutionary algorithms to the synthesis of robot controllers, and sometimes robot morphologies (Nolfi and Floreano, 2000). In ER, the evolutionary process is typically driven towards solutions for a task according to a manually crafted fitness function (Nelson et al., 2009). Evolutionary algorithms driven by a fitness function are, however, vulnerable to deception and convergence to local optima (Whitley, 1991). Common approaches to overcome these issues are based on diversity preservation. Traditionally, diversity is preserved at the genomic level (Goldberg and Richardson, 1987). However, in ER it has been observed that many different genotypes can represent similar behaviours, and that small changes in the genotype can lead to substantial changes in behaviour (Mouret and Doncieux, 2012). Therefore, recent works have proposed the use of behaviour similarity measures (BSM) in the evolutionary process to promote an effective diversity in the population.

A number of different strategies using BSM have been proposed. The most popular approach, novelty search, directly rewards individuals that display novel behaviours (as measured by the BSM), instead of using a fitness function (Lehman and Stanley, 2011; Mouret and Doncieux, 2012). BSM have also been used to speciate the population according to the behaviour of the individuals (Trujillo et al., 2011; Moriguchi and Honiden, 2010). Ollion and Doncieux (2011) defined a measure for the degree of behaviour space exploration, based on BSM, and used the measure to predict the relative performance of different evolutionary setups.

Devising effective behaviour measures is not straightforward (Savage, 2004), since the measure must be able to capture the details of the behaviour that are relevant in the given task, while at the same time should contain no or as few irrelevant behaviour features as possible. Behaviour measures are typically defined by the experimenter based on task-specific knowledge (for examples, see Mouret and Doncieux, 2012; Lehman and Stanley, 2011; Mouret and Doncieux, 2009; Gomes et al., 2013). Relying on the experimenter's intuition about the task may, however, introduce biases in the evolutionary process. These biases can compromise the evolutionary search, as the experimenter might not know beforehand what type of behavioural traits should be explored in order to solve the task.

Several researchers have proposed the use of *generic* BSM (Doncieux and Mouret, 2010; Gomez, 2009; Gomes and Christensen, 2013) for ER. Generic measures do not rely on the specific details of a task, and can be used throughout the domain. Their use is, however, associated with two key issues: (i) generic measures are only weakly related with the specific task, which can create an unnecessarily large behaviour space (Cuccu and Gomez, 2011), and (ii) they are mostly unintelligible, undermining analysis and comprehension of the behaviour space exploration.

We propose a new class of behaviour measures, *system-atically derived behaviour characterisations* (SDBCs), that combine the advantages of task-specific and generic measures. The proposed measures are directly derived from a formal description of the task state. This way, we reduce the dependency on the experimenter's knowledge about the task while, at the same time, obtain characterisations that are

directly related to the task. In this paper, we apply SDBCs to robotics tasks, but the approach could potentially be generalised to other types of agent-based systems, as the formal task description resembles the SMART agent framework (d'Inverno et al., 2004). We augment our method with the inclusion of a weighting scheme for behaviour features, based on the estimated relevance of the features.

The proposed measures are evaluated with novelty search in three simulated collective robotics tasks: resource sharing, gate escape, and predators-prey pursuit. We compare the proposed measures with behaviour characterisations defined based on task-specific knowledge.

Related Work

Task-specific distance measures

Most previous works on behavioural diversity rely on behaviour characterisations designed specifically for the given task. These characterisations are composed of behavioural traits that the experimenter considers relevant for describing agent behaviour in the context of the given task. The behavioural distance then corresponds to the Euclidean distance between the characterisation vectors. Table 1 lists several examples of characterisations that have been used in previous ER studies. Analysing these characterisations, the following commonalities can be identified:

- There is a strong focus on the spatial relationships between entities in the task environment (1, 2, 5, 6, 8, 9).
- Characterisations often comprise only a small number of different behavioural traits (1, 3–5, 7–9).
- Many characterisations focus on the final state of the environment (1, 3–5, 7–9), values averaged over an entire trial (7–9), or a single quantity sampled over time (2, 6).

Generic distance measures

Gomez (2009) proposed the use of generic measures for assessing behaviour similarity. In the proposed approach, action records for the agents are compared, using either the Hamming distance, relative entropy, or normalised compression distance (NCD). Doncieux and Mouret (2010) extended generic measures to evolutionary robotics, proposing the following BSMs:

Hamming distance: Distance between the sequence of all the binary sensor and effector values of the agent sampled through time.

DFT: A discrete Fourier transform is applied to the sensor-effector sequence, and the first coefficients are used to compute the distances between individuals.

State count: Each possible sensor-effector state corresponds to one entry in a vector. Each entry contains the number of times the corresponding state was visited.

Gomes and Christensen (2013) extended the *Hamming distance* and *state count* measures, making them applicable to multiagent systems and non-binary sensors and effectors.

Common to all generic measures is that they rely exclusively on the sensor-effector states of the agents. While this design makes the measures generic and widely applicable, as any robotics experiment involves robots with sensors and effectors, it also represents their main weakness. Since there is no direct relationship between a given task and the generic behaviour characterisation, the behaviour space is typically very large, which can compromise the performance of diversity-based techniques (Cuccu and Gomez, 2011; Mouret, 2011). Additionally, the characterisations are mostly unintelligible, since they are not intrinsically related to observable characteristics of the agent's behaviour.

Mouret and Doncieux (2012) compared task-specific and generic characterisations in a comprehensive empirical study with a number of single-robot tasks. Doncieux and Mouret (2013) showed how different similarity measures (generic or task-specific) can be combined, by either switching between them throughout evolution or by calculating the behaviour distance based on all similarity measures.

Novelty search

To evaluate the proposed SDBCs, we use novelty search to evolve controllers for three distinct multirobot tasks. In novelty search (Lehman and Stanley, 2011), individuals are scored according to a *novelty metric*, instead of how well they perform a given task.

The novelty metric quantifies how different an individual is from other, previously evaluated individuals with respect to behaviour. The metric relies on the mean behaviour distance (as given by the BSM) of that individual to the k nearest neighbours. Potential neighbours include the other individuals of the current population and a sample of individuals from previous generations stored in an archive. Candidates from sparse regions of the behaviour space therefore tend to receive higher novelty scores, generating a constant evolutionary pressure towards behavioural innovation.

As novelty search is guided by behavioural innovation alone, its performance can be greatly affected by the size and shape of the behaviour space. In particular, behaviour spaces that are vast or contain dimensions not related with the task can cause novelty search to perform poorly (Cuccu and Gomez, 2011; Mouret, 2011; Gomes et al., 2012). To address this issue, we augment novelty search and include a fitness objective, as suggested in (Mouret, 2011; Mouret and Doncieux, 2012).

Systematically Derived Behaviour Characterisations – SDBC

In the analysis of the task-specific behaviour characterisations used in previous works, it can be observed that the characterisations are generally composed of relatively simple behavioural features (see Table 1). Based on these regularities, we formalise a workflow for the definition of behaviour characterisations. We show how such workflow can

be used to systematically derive behaviour characterisations with minimal dependence on the experimenter's understanding of the task.

The proposed workflow is summarised in Figure 1. The interface between the specific task and the derivation of the behaviour characterisations is accomplished through a formal description of the current state of the task (1) that should be specified by the experimenter. At each simulation step, a set of behaviour features is extracted from the formal task state (2). After the simulation has ended, the behaviour feature samples are combined to assemble a fixed-length raw characterisation vector (3). Based on all the raw characterisation vectors obtained in the current population, a set of standardisation coefficients is calculated (4), and optionally, a set of feature weights (5). The raw characterisations are then transformed with the standardisation coefficients (6) and feature weights (7). The behaviour distance between individuals is then given by the Euclidean distance between the respective transformed characterisation vectors. Below, we present the task description formalism and details on each step in the workflow.

Task state formalism

The task state formalism separates the specific task details from the method used to devise behaviour characterisations, thus reducing the dependence on the experimenter.

The proposed formalism makes no distinction between agents and environmental features, both are treated equally as *entities* of the task. Each entity $e \in E_{\kappa}$ is associated with a κ -tuple of state attributes (ϑ) , and a tuple x with the constant properties of the entity. The tuple ϑ is composed of the properties of the entity that can change during task execution. To encompass multiagent tasks, we introduce the concept of *entity group*. An entity group $g \in G$ can be formed by an arbitrary number of entities that share the same type and number (κ) of attributes. The cardinality (η) of a group can change during the task, and a single agent can constitute a group. The experimenter should provide the minimum (η_{min}) and maximum (η_{max}) size of each group.

A task state is composed of (i) a list of entity groups, and (ii) a distance function f_D . The function f_D should measure or estimate the physical distance between any two entities. A task state T is thus defined by:

$$T = \langle g_1, \cdots, g_N, f_D \rangle , g_i \in G$$

$$G = \{ \langle e_1, \cdots, e_\eta \rangle \mid e_i \in E_\kappa \land \eta \in [\eta_{min}, \eta_{max}] \}$$

$$E_\kappa = \{ \langle \vartheta, x \rangle \mid \vartheta \in \mathbb{R}^\kappa \}$$

$$f_D : E_\kappa \times E_{\kappa'} \to \mathbb{R}$$

$$(1)$$

Extraction of behaviour features

At each time step, we automatically extract a set of behaviour features from the formal task state. These features correspond to a high-level description of the agents' behaviour and environment's state. They measure spatial relations between agents of the same entity group and between different groups, and the mean state of each group. Previous work (Gomes et al., 2013) has shown that averaging behaviour features over a group's agents can lead to effective and scalable characterisations for multiagent systems. We defined the following behaviour features:

• Size of each entity group, relative to the respective limits:

$$S_g = \frac{|g| - \eta_{min_g}}{\eta_{max_g} - \eta_{min_g}}, g \in G \land \eta_{max_g} > \eta_{min_g}$$
 (2)

• For each entity group, mean state of the entities:

$$\vartheta_g = \left\langle \sum_{e \in g} \frac{\vartheta_e[1]}{|g|}, \cdots, \sum_{e \in g} \frac{\vartheta_e[\kappa]}{|g|} \right\rangle, g \in G \quad (3)$$

 For each entity group, mean distance of each entity to the other entities of the same group (a measure of dispersion):

$$D_g = \sum_{e_i \in g} \sum_{e_j \in g, j \neq i} \frac{f_D(e_i, e_j)}{(|g| - 1)^2} , g \in G \land |g| > 1 \quad (4)$$

• Mean pairwise distance between each two entity groups:

$$R = \langle d(g_1, g_2), \cdots, d(g_1, g_N), \cdots, d(g_{N-1}, g_N) \rangle$$

$$d(g_a, g_b) = \sum_{e_i \in g_a} \sum_{e_j \in g_b} \frac{f_D(e_i, e_j)}{|g_a||g_b|}, a \neq b$$
(5)

Aggregation of feature samples

After a simulation has ended, the samples obtained for each behaviour feature at each time step are aggregated to assemble a fixed-length characterisation vector. Inspired by the task-specific characterisations used in previous work (see Table 1), a concatenation of the mean and final values of each behaviour feature is performed. The duration of the simulation is additionally included as a feature in the characterisation.

Feature standardisation

The behaviour characterisations can be composed of features that have different nature and thus have very distinct ranges. To overcome this disparity, the characterisations of the current population are standardised with the same set of coefficients at every generation. If a novelty archive exists, it also needs to be updated with those coefficients. Each behaviour feature k of a vector b is standardised according to:

$$b_k' = (b_k - \mu_k)/\sigma_k \quad , \tag{6}$$

where μ_k and σ_k are respectively the mean and standard deviation of feature k.

Feature weighting

Previous work has shown that behaviour features weakly related with the task might be harmful (Gomes et al., 2013). We therefore propose and evaluate a method for weighting the behaviour features according to their estimated relevance to the task. Relevance is estimated based on *mutual information feature selection (MIFS)* (Battiti, 1994) — a machine learning feature selection algorithm. Mutual information is a quantitative measurement of how much one random variable tells us about another random variable. In the proposed

approach, the relevance of each behaviour feature is estimated according to the mutual information between the feature values and the fitness scores of the individuals. Since the fitness score typically reflects the degree of fulfilment of a given task, this measure estimates the relevance of each behaviour feature with respect to the solution of the task.

Each behaviour feature is assigned a weight equal to the mutual information estimate plus a minimum weight δ . Therefore, the higher the mutual information, the higher the impact of that behaviour feature in the distance measure. The added minimum feature weight guarantees that none of the behaviour features is completely ignored. Each feature k of a characterisation b is weighted according to:

$$b_k' = b_k \cdot [\delta + I(F;k)] \quad , \tag{7}$$

where I(F;k) is an estimate of the mutual information between the fitness scores (F) and the behaviour feature k, and δ is the minimum feature weight. We set $\delta=0.25$ in all experiments, which is relatively small when compared to the typical mutual information scores of the more relevant features. Values of 0, 0.1 and 0.5 were also tested, but they yielded no improvements.

Behaviour feature weights have to be periodically updated throughout evolution. For scalability purposes, we only use the current population to calculate the weights. The computational complexity associated with weights calculation could be further reduced by performing updates less frequently, every n generations, for instance.

Experimental Setup

We use three different tasks to evaluate the general applicability of our approach. The performance of SDBCs is compared with task-specific characterisations and fitness-based evolution. For the resource sharing task and predator-prey pursuit, we use task-specific characterisations that have been fine-tuned in previous works. In all tasks, the robots are homogeneous, i.e., the same neural network is copied to each robot of the group for evaluation. Each controller is evaluated in 10 simulations with randomised initial conditions.

Gate escape task

In this task, a group of robots must escape through a narrow gate that closes shortly after the first robot has passed. To solve the task successfully, the robots must first find the gate, and then wait for each other before starting to pass through the gate. The task is detailed in Figure 2 (top-left) and Table 2. The fitness function F_q is given by:

$$F_g = \frac{g + t/\tau}{1 + N} \ , \tag{8}$$

where g is the number of robots that escaped through the gate, t is the simulation length, τ is the maximum simulation length, and N is the total number of robots. The task-specific behaviour characterisation is a vector of length four

comprising the following behavioural features (normalised to [0,1]): (i) number of escaped robots; (ii) time when the gate opened; (iii) mean distance to the gate; and (iv) mean dispersion of the robots.

The task state T_g is composed of three entity groups: (i) the group of the robots that have still not passed through the gate; (ii) the gate; and (iii) the walls. Each robot has five attributes: its x and y position, turning speed, linear speed, and whether it is currently passing through the gate or not. The gate has one state variable, denoting whether it is closing or not. The surrounding walls are stateless.

Resource sharing task

In the resource sharing task (Gomes et al., 2013; Gomes and Christensen, 2013), a group of robots must coordinate in order to allow each member periodical access to a single battery charging station. The energy consumption varies with the motor speed, and the charging station can only hold one robot at a time. The task is detailed in Figure 2 (top-right) and Table 2. The fitness function F_s is given by:

$$F_s = \frac{s + \overline{e}/e_{max}}{1 + N} \quad , \tag{9}$$

where s is the number of surviving robots, \overline{e} is the mean energy of the robots throughout the simulation, and N is the number of robots. The task-specific characterisation was proposed in (Gomes et al., 2013): a vector of length four, composed of: (i) the number of surviving robots; (ii) the mean energy of the robots; (iii) the mean movement speed; and (iv) the mean distance of the robots to the charging station. Each of these elements is normalised to [0,1].

The task state T_s is composed by two entity groups: (i) the group of alive robots; and (ii) the charging station. Each robot has six attributes: its x and y position, turning speed, linear speed, current energy level, and whether it is currently charging. The charging station has a single state variable indicating whether it is currently charging a robot or not.

Predator-prey pursuit

In the predator-prey task, three predators have the objective of capturing a single prey, i.e., one predator should physically touch the prey. The predators can sense one another. The simulation ends if the prey escapes the chase zone. Only the predators' controller is evolved, and the behaviour of the prey is preprogrammed: the prey moves away from nearby predators at full speed, and stops moving when it does not sense any predators. The task is detailed in Figure 2 (bottom) and Table 2. The fitness function F_p is given by:

$$F_p = \begin{cases} 2 - t/\tau & \text{if prey captured} \\ max(d_i - d_f, 0)/size & \text{otherwise} \end{cases} , (10)$$

where t is the simulation length, τ is the maximum length, d_i is the mean initial distance from the predators to the prey, d_f

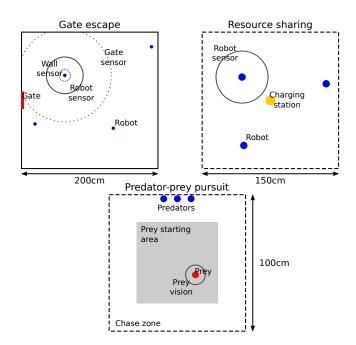

Figure 2: Initial simulation conditions. In the predators-prey task, the predator's initial position is fixed. In the other two tasks, the robots are placed randomly in the environment.

Gene mutation rate

is the mean final distance, and size is the arena's diagonal. The task-specific characterisation (Gomes et al., 2014) is a vector of length four, with all elements normalised to [0,1]: (i) whether the prey was captured or not; (ii) the simulation length; (iii) the mean final distance of the predators to the prey; and (iv) the mean distance of the predators to their centre of mass (dispersion) throughout the simulation.

The task state T_p is composed of three entity groups: (i) the group of the predators; (ii) the prey; and (iii) the chase zone boundaries. Both the predators and the prey have the same attributes: x and y location, turning speed, and linear speed. The environment is stateless.

Evolutionary setup

We used a canonical generic algorithm, where the neural network weights are directly encoded in the chromosomes. The parameters of the genetic algorithm and novelty search are listed in Table 2. All evolutionary treatments use the same parameters. The individuals are scored with a multi-objectivisation of novelty and fitness scores: at each generation, the individuals are sorted according to their Pareto front and crowding distance (Deb et al., 2002), considering the fitness and novelty objectives.

Results and Analysis

Quality of the solutions

We compare fitness-driven evolution (*Fit*) to novelty search with the three behaviour characterisation approaches: task-specific characterisations (*NS-TS*), SDBC with feature weighting (*NS-SD*+), and SDBC without weighting (*NS-SD*). Figure 3 shows the highest fitness scores achieved with each approach, in each of the three tasks.

The distribution of the highest fitness scores achieved by Fit displays a high variance, since all tasks have some degree of deception and Fit often converges to local optima. NS is unaffected by deception, and all variants achieve significantly higher fitness scores than Fit (Mann-Whitney U test, p-value < 0.05). The scores achieved by NS-TS are on average superior to NS-SD+ in the gate escape (p-value = 0.013) and resource sharing tasks (p-value = 0.025). The difference is, however, relatively small, and visual inspection of the solutions revealed no clear difference between the best controllers evolved by NS-TS and NS-SD+.

Across the three tasks, the use of feature weighting never harms the performance of SDBCs, and NS-SD+ is on average superior to NS-SD. Significant differences between NS-SD and NS-SD+ are, however, only present in the resource sharing task (p-value < 0.01). What makes NS-SD+ superior in this particular task is not evident, and additional experiments are needed to clarify the potential advantage provided by the weighting scheme. In the following sections, we analyse the weighting scheme and what impact it has on behaviour exploration.

Relevance of behaviour features

Following Equations 2–5, and the task descriptions presented in the Experimental Setup, a total of 10 behaviour features were extracted for the gate-escape task, 10 features for the resource sharing task, and 13 features for the predator-prey pursuit. After the feature sample aggregation process, this resulted in behaviour characterisations of lengths 21, 21, and 27, respectively.

Since feature extraction is systematic, it is important to determine if the behaviour features can adequately characterise the behaviour of the individuals in the context of the given task. Table 3 lists the mutual information scores of the

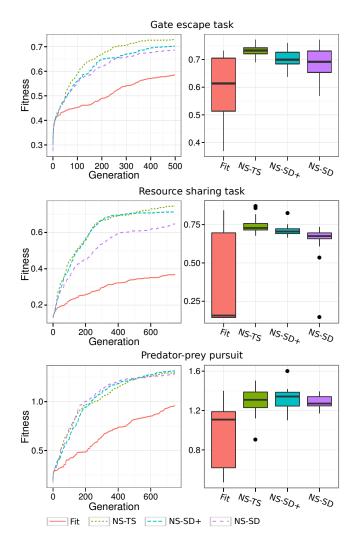

Figure 3: Left: highest fitness scores found at each generation, averaged over 20 evolutionary runs for each method and task. Right: boxplots of the highest fitness scores found in each evolutionary run. The whiskers are the extreme values within 1.5 IQR and the dots are outliers.

most relevant features for each task. It can be observed that some of the behaviour features match the features defined in the task-specific characterisations (highlighted in the table with a tick). The remaining features correspond to behavioural traits that are intuitively related with the fulfilment of the task. The relevance of each feature is also consistent across the multiple evolutionary runs, as indicated by the relatively small standard deviations of the means.

Our results suggest that the mutual information between feature values and fitness scores is a good indicator of the relative relevance of each behaviour feature to task fulfilment. Furthermore, the analysis shows that the systematically derived characterisations include highly relevant behaviour features for the given tasks. This explains why the performance of novelty search with systematically derived

Table 3: Mutual information (MI) between behaviour features and fitness scores, averaged over each evolutionary run (*Mean MI*). The standard deviation is shown in the *SD MI* column. Only the features with highest MI scores are shown. (*F*) marks features measured at the final state, while (*M*) marks features averaged over simulation time. The rightmost column indicates if a similar feature is present in the corresponding task-specific characterisation.

characterisations is very similar to novelty search with characterisations specifically designed for each task.

Behaviour space exploration

We analysed the exploration of the behaviour space to determine the underlying differences between the novelty search variants. The behaviour space was built with the SDBC features. We used a Kohonen map to reduce the dimensionality of the space for visualisation purposes. The resulting plots for the resource sharing task can be seen in Figure 4. The results for the other two tasks are similar.

Fitness-based evolution typically explores only a narrow region of the behaviour space, which translates to premature convergence and in turn leads to an inferior performance. All novelty search variants explore the behaviour space more uniformly. The behaviour exploration in *NS-SD*+ follows a pattern similar to *NS-TS*, but with a slightly inferior focus on the high-fitness behaviour region (highlighted in the maps). Regarding the influence of the weighting scheme, it is clear that *NS-SD*+ spends more effort in the high-fitness region, when compared to *NS-SD*. The behaviour exploration of *NS-SD* is the most uniform since there are no bias towards

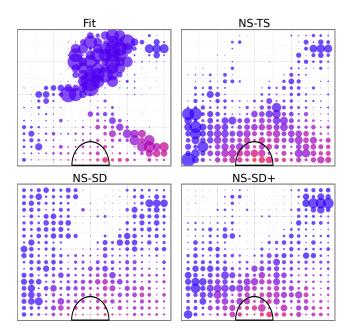

Figure 4: Average behaviour space exploration in the resource sharing task. The bigger the circles, the higher the exploration in that specific behaviour region. The behaviour region associated with the highest fitness scores is highlighted with a semicircle (bottom-middle).

specific behaviour dimensions. The absence of bias causes *NS-SD* to explore a behaviour region to which none of the other methods devoted significant effort (top-left corner in the maps). These results suggest that although there was no significant difference between *NS-SD*+ and *NS-SD* in terms of solutions' quality (see Figure 3), the weighting scheme can actually focus behaviour exploration in the most relevant regions.

Conclusion

We proposed an approach for systematically deriving behaviour characterisations (SDBCs) for evolutionary robotics. The proposed approach relies on a formal description of the task state. Behaviour features are systematically extracted based on the state of the agents, their environment, and the spatial relationships between the physical entities of the task. We also proposed a feature weighting scheme that estimates the relevance of the extracted features, based on the mutual information between feature values and fitness scores. We demonstrated the proposed approaches with novelty search, using three different simulated collective robotics tasks.

Our results showed that SDBCs are on par with task-specific characterisations, with the advantage of relying less on the experimenter's task-specific knowledge. The quality of the evolved solutions is similar, and the behaviour space exploration with task-specific characterisations was similar to SDBCs with the weighting scheme. Analysing the most

relevant behaviour features present in SDBCs, we could observe that they either match features of the task-specific characterisation or correspond to behavioural traits that are highly related to solving the task. While the calculated relevance scores are in accordance with our understanding of the tasks, using these scores to weight the characterisations did not translate in a significant advantage in terms of the fitness scores achieved. Our results did, however, show that feature weighting helps focus the exploration on more relevant behaviour regions and more effort is spent in regions associated with high fitness scores.

In light of our results, we consider that the proposed systematic approach represents a promising way of defining behaviour characterisations. SDBCs reduce the dependency on the experimenter's intuition about the task, thus introducing fewer biases in behaviour exploration. Nevertheless, the systematically derived characterisations contain behaviour features that are highly related to the specific task, and can accurately capture the behaviour of the individuals. The approach is flexible and extensible, and can potentially accommodate the specific details of many tasks, possibly even outside the domain of embodied agents.

Possible extensions of the proposed approach include: (i) extraction of additional features from the task state, e.g., by measuring inter-group relations between attributes of the same type; (ii) improved strategies for combining the behaviour feature samples obtained during task execution, e.g., through function approximation or time discretisation; and (iii) more elaborate weighting schemes, that could for example eliminate redundancy between behaviour features.

Abstract

The embodied cognition paradigm emphasizes that both bodies and brains combine to produce complex behaviors, in contrast to the traditional view that the only seat of intelligence is the brain. Despite recent excitement about embodied cognition, brains and bodies remain thought of, and implemented as, two separate entities that merely interface with one another to carry out their respective roles. Previous research co-evolving bodies and brains has simulated the physics of bodies that collect sensory information and pass that information on to disembodied neural networks, which then processes that information and return motor commands. Biological animals, in contrast, produce behavior through physically embedded control structures and a complex and continuous interplay between neural and mechanical forces. In addition to the electrical pulses flowing through the physical wiring of the nervous system, the heart elegantly combines control with actuation, as the physical properties of the tissue itself (or defects therein) determine the actuation of the organ. Inspired by these phenomena from cardiac electrophysiology (the study of the electrical properties of heart tissue), we introduce electrophysiological robots, whose behavior is dictated by electrical signals flowing though the tissue cells of soft robots. Here we describe these robots and how they are evolved. Videos and images of these robots reveal lifelike behaviors despite the added challenge of having physically embedded control structures. We also provide an initial experimental investigation into the impact of different implementation decisions, such as alternatives for sensing, actuation, and locations of central pattern generators. Overall, this paper provides a first step towards removing the chasm between bodies and brains to encourage further research into physically realistic embodied cognition.

Introduction and Background

The fields of evolutionary robotics and artificial life have seen a great deal of emphasis on embodied cognition in recent years [Cheney et al. (2013); Bongard (2013); Rieffel et al. (2013); Auerbach and Bongard (2012); Hiller and Lipson (2012a); Lehman and Stanley (2011); Auerbach and Bongard (2010a,b); Pfeifer et al. (2007); Hornby et al. (2001); Lipson and Pollack (2000)]. There is even a paradigm called *embodied cognition*, which argues that the specifics of the embodiment (such as the morphology) are

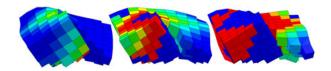

Figure 1: Current flowing through an evolved creature. The legend for voltage within each cell (colors) is given in Fig. 3.

vital parts of the resulting behavior of the system: It argues that the co-evolutionary connection between body and brain is more deeply intertwined than the body simply acting as a minimal physical interface between the brain and the environment [Pfeifer and Bongard (2006)].

Recent work in evolutionary robotics has shown that complex behaviors can arise when co-evolving bodies and brains. At one end of the spectrum, Auerbach and Bongard (2010b) demonstrated the evolution of physical structures that had no joints or actuators, and evolved to cover the largest distance in a controlled fall due to gravity. While that work exemplifies the evolution of behavior emerging from morphology alone, it does not co-evolve any actuation or control. Auerbach and Bongard (2010a) then evolved the placement of CPG controlled rotational joints between cellular spheres, thus co-evolving morphology and control.

Cheney et al. (2013) evolved locomoting soft robots made of multiple different materials: two passive voxels of differing rigidity and two actuated voxel types that expanded cyclically via out-of-phase central pattern generators (CPGs). While this work added a variety of soft materials and a new type of actuation, the pairing of muscle types directly to a CPG again reflected a focus on evolving morphology rather than sophisticated neural control.

Many examples in the literature include the co-evolution of a robot morphology with an artificial neural network controller [Sims (1994); Lipson and Pollack (2000); Hornby et al. (2001); Lehman and Stanley (2011)]. These studies (and many more like them) involve what might be called "ghost" networks: artificial neural networks that provide control to the body, yet do not have any physical embodi-

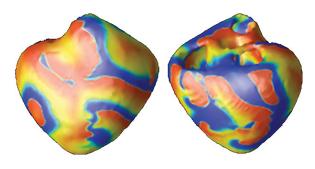

Figure 2: An example of complex electrical wave propagation in cardiac modeling [Fenton et al. (2005)].

ment in the system they control. The state of input nodes to these networks is often set by sensors in the robot and output nodes typically signify behavioral outcomes in the actuators, but the computation is done supernaturally, disjoint from the body itself.

In the age of 3D printing, it is a realistic goal for robots to physically walk out of a printer. It is thus worthwhile to consider designing robots that can be physically realized: i.e., those whose controllers are accounted for by being physically woven into the design of the robot.

While the brains of animals are often a separate module within their bodies, animals also have central and peripheral nervous systems extending throughout their bodies. An extreme example of this is the octopus, which has as much as 90% of its neurons existing outside of its central nervous system [Zullo et al. (2009)]. The distributed and physical layout of the nervous system over space may contribute significantly to neural processing, as the delays and branching in axons (the basis for nerves) are suggested to serve computational functions [Segev and Schneidman (1999)].

Despite the prevalence of embodied, distributed circuitry in nearly all of animal life, the idea of an embodied nervous system has been absent from the field of evolutionary robotics. The sub-field called Evolvable Hardware evolves physical circuits for computer chips [Floreano and Mattiussi (2008)], but such work has not been applied to evolving the circuitry of artificial life organisms. We are unaware of work with virtual creatures that have physically embodied control systems (e.g. where neural circuitry physically runs throughout the body of the creature). We present the first such work in this paper.

We propose a very basic model of electrical signal propagation throughout the body of an evolved creature. This embodied controller is based on electrophysiology (specifically at large scales, such as cardiac electrophysiology, Fig. 2). Electrophysiology is the study of the electrical properties of biological cells and tissues [Hoffman et al. (1960)]. In this model, electrical pulses from a single centralized sinusoidal pacemaker (analogous to the sinoatrial node – the pacemaker in the heart [Brown (1982)]) are propagated through the

electrically conductive tissue of the creature. The location and patterning of this conductive tissue is described by an evolved Compositional Pattern Producing Network (CPPN) genome. Evolution controls the shape of the body and the electrical pathways within it, which both combine to determine the robot's behavior.

The model involves conductive tissue cells that collect voltage from neighboring cells, causing an action potential (spike) if the collected voltage exceeds the cell's firing threshold (Fig. 3). Once this threshold is crossed, the cell depolarizes, causing a voltage spike that excites neighboring cells. This voltage spike is followed by a refractory period, during which the cell is temporarily unable to be re-excited.

This model allows for the propagation of information through the body of the creature in the form of electrical signals. The structure of this flow is produced entirely by the topology of the creature and the state of each cell's direct neighbors. In this sense, the model can be seen as a form of distributed information processing. One could draw similarities between this model and a 3D-grid of neurons, where each neuron receives inputs from, and has outputs to, its immediate neighbors. In this analogy, we are evolving where neurons should exist in the grid, what type of material the neuron is housed in, as well as the material type, if any, of grid locations that do not contain neurons.

The placement of material, which is under evolutionary control, directly determines the resultant behavior of the organism. Cells that actuate will contract and expand as they depolarize (much like the contraction of cardiac muscles), leading to the locomotion behavior of the creature. In order to control the signal flow throughout the creature, insulator cells are allowed, which are unable to accept and pass on the signal. Evolution can also choose not to fill a voxel with material. The morphology of the simulated robot and tissue type at each cell is determined by a CPPN genome.

This model examines the evolution of embodied cognition at a more detailed level of implementation than is typical in the literature – with embodied control circuitry resulting directly from the morphology of the individual creature. While this study only covers the classic problem of locomotion, it is a step towards truly physically embodied robots.

Methods

CPPN-NEAT

The evolutionary algorithm employed in this study is CPPN-NEAT. This algorithm has been previously described in detail (Stanley, 2007, 2006; Auerbach and Bongard, 2010b; Cheney et al., 2013), so it is only briefly described here.

A Compositional Pattern Producing Network (CPPN) [Stanley (2007)] is variation of an Artificial Neural Network (ANN) [McCulloch and Pitts (1943); Floreano and Mattiussi (2008)] where each node can have one of many mathematical functions as an activation function (e.g. sine, cosine, Gaussian, sigmoid, linear, square, or positive square root)

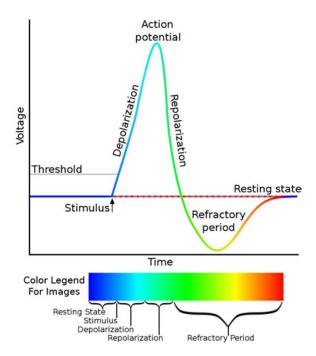

Figure 3: (top) A depiction of an action potential. Notice how the voltage is below the threshold until a stimulus event (such as a pacemaker or neighboring cell spike) pushes the voltage to the threshold value. Once this threshold is met, a voltage spike occurs via a process called depolarization. The cell excites its immediate neighbors during this process. Following the action potential, the cell enters a fixed length refractory period, during which it is physically unable to produce a new action potential. Finally, the cell returns to its resting state, able to start the process again when a new stimulus arrives. (bottom) These phases of the action potential cycle are mapped to the color code used to visualize the soft robots in Figs. 1, 4, and 5. Image licensed via Creative Commons.

instead of being limited to a sigmoid activation function. In CPPN-NEAT, a design space is discretized into individual locations (in this case a 3D space is discretized into a $10 \times 10 \times 10$ grid of voxels, for 1000 total voxels). The CPPN is queried once per voxel to determine the phenotypic state at that location (in this case, whether a voxel is present and, if so, the material type). The inputs to the CPPN network for each location are different: specifically, they include one input node for each dimension of the space (here, reporting the x, y, and z values of that location), as well an input that reports the distance (d) from the center to the location. The network also features output nodes for each material property. There are three in this study: one node specifies if a voxel exists at the queried location, the second decides if the material at that location is conductive, and the third decides whether or not the material is an actuated muscle (the latter two only matter if the voxel is present).

Conductive VoxCad

Fitness is evaluated in the VoxCad soft body simulator [Hiller and Lipson (2014)]. Its dynamics have previously allowed the evolution of complex and lifelike behaviors in soft robots, as it can simulate muscle contractions [Cheney et al. (2013)]. Further details about VoxCad can be found in Hiller and Lipson (2012b).

This work adds electrophysiology to VoxCad by adding a simple action-potential model, acting on the scale of a single voxel (analogous to a cell). Each voxel has an immediate membrane potential level (the difference between the electric potential inside and outside the cell), as well as a threshold membrane potential level. In an action-potential model (Fig. 3), a cell's resting potential is below that of the threshold potential. When the membrane potential reaches its threshold value, the cell depolarizes, causing a spike in the cell's membrane potential and voltage.

Following the depolarization, the cell hyperpolarizes, dropping the voltage and membrane potential below their original values, as the cell enters a refractory period. During this refractory period, the cell is unable to be depolarized again. In biological cells, the refractory period also consists of a relative refractory period when the cell is able to be depolarized, but only by unusually high voltage levels. For simplicity, we ignore this aspect in our model, and consider only the absolute refractory period, during which depolarization is disallowed. This refractory period means that the current is unable to flow backwards towards recently depolarize cells, causing the unidirectional propagation of action potentials in a wave across the cells.

A cell's action potential (starting with the beginning of the depolarization phase in Fig. 3) triggers a sinusoidal expansion/contraction of that cell with a maximum amplitude of 39% linear expansion per voxel side.

A given cell may transmit current to any other cell that it is physically touching. In 3D, this rule means that up to 26 neighboring voxels (the "Moore neighborhood") can be activated by a single voxel. The threshold potential of each cell is set such that it will be excited if, and only if, at least one of its neighboring cells undergoes an action potential that causes that cell's voltage to spike. The time it takes a cell to excite its neighbor is half of its depolarization period. This delay in excitation means that the electric signal does not instantly activate all contiguously connected cells, but rather spreads outwards in a wave-like pattern of muscle actuation.

Cells may be of any of the following types: empty, conductive muscles, insulating muscles, conductive passive tissue, insulating passive tissue, or a pacemaker cell. Near the center point of the discretized $10\times10\times10$ design space, a lone pacemaker is placed (cell number 555 out of 1000). Analogous to the sinoatrial node in cardiac electrophysiology, this pacemaker node serves as the source of electric stimulation for the entire system. Insulating cells are similar to the cells explained above, except that they are unable to

accept current from neighboring cells and thus never reach their threshold potential or produce an action potential.

In this model, the refractory period lasts 5 times as long as the depolarization period. This means that at least 5 voxels must separate the leading edges of two serial action potential waves. Since the pacemaker is placed in the center of the $10 \times 10 \times 10$ space, approximately one wave of action potentials would exist at any given time in a setup with a uniform cube of entirely conductive material – where a wave of action potentials would propagate uninterrupted, with a new one starting around the time the first reaches the outer edge of the space. We chose this setup to encourage the evolution of static gaits, which can be more robust and transferable to reality than dynamic gaits [Belter et al. (2008)].

The length of the expansion/contraction period of each node is set equal to the refractory period, such that each cell is guaranteed to be fully returned to its original size before its next actuation cycle begins.

Task and Fitness Evaluation

Following Cheney et al. (2013), we evolve these electrophysiological robots for locomotion over flat ground. This simple task and environment make fitness evaluation easy. Despite its simplicity, the task is a classic problem in the field, and has been repeatedly shown to produce an array of complex morphologies and interesting behaviors [Cheney et al. (2013); Clune et al. (2009, 2011); Auerbach and Bongard (2014); Lehman and Stanley (2011)].

Each creature is simulated for 20 times the length of an expansion/contraction cycle. Its displacement between the starting coordinates and the creature's final center of mass (in the xy plane) is recorded. In an effort to discourage designs that might excite as many cells as possible, and to encourage designs with sparse spindles of connectivity (similar to the peripheral nervous system), the distance traveled is multiplied by $1 - \frac{(\# \ of \ conductive \ cells)}{1000}$. Thus the fitness function incentivizes minimizing the amount of conductive tissue and maximizing the distance traveled. While a multi-objective technique may be ideal in finding the optimal tradeoff between these goals, we follow previous CPPN-NEAT research in using this single, multi-part fitness function [Cheney et al. (2013); Auerbach and Bongard (2009)].

Experimental Parameters

Unless otherwise noted, each treatment described below consists of 48 independent runs (with identical initial conditions across treatments). Each run consists of a population size of 30 individuals evolved for 1000 generations. Unless otherwise noted, all other parameters are consistent with Cheney et al. (2013).

Statistical Reporting

Because the data are not normally distributed, all plots show median fitness (thick, center lines) bracketed by two thin lines that represent 95% bootstrapped confidence intervals of the median [Sokal and Rohlf (1995)]. For the same reason, all *p*-values are generated with the non-parametric Mann-Whitney-Wilcoxon Rank Sum test, which does not assume normality. Reported *p*-values compare the distance traveled by the top organism for each of the 48 runs at the final (1000th) generation. Plots report distance traveled, not adjusted fitness (which penalized for the number of conducting voxels as explained previously).

Results

Since this is the first study of evolved electrophysiological robots, there are many unanswered questions regarding the design and implementation of such a system. Many arbitrary design choices were made during the initial implementation. Here, we examine the impact of some of these choices.

As with many explorations in evolved virtual organisms, one of the main goals is complex, natural-appearing behavior. However, there are no satisfactory metrics for the "naturalness" or complexity of evolved behaviors. For this reason, we must rely on our qualitative, subjective assessments. A video of the evolved behaviors can be seen on the "Cornell Creative Machines Lab" Youtube channel, or found directly at this link: http://goo.gl/CvJp4. We believe the behaviors are interesting, complex, and lifelike – at least as much as in Cheney et al. (2013) – despite the added challenges of evolving physically embedded control.

We observed that physically instantiated control circuitry can produce both predictable and chaotic behaviors. Fig. 4 shows a simple wave of action potentials propagating outwards from the center of the creature, with little interruption. Fig. 5 reveals the evolution of unpredictable physical dynamics that still produce functional behavior. Notice the multiple "inputs" to a potential self-sustaining circular pathway. Fig. 1 demonstrates a circular actuation pattern of intermediate complexity, due more so to changes in the robot's shape than to material differences within it. We now turn to more quantitative analyses.

Pacemaker Placement

The placement for the pacemaker was an arbitrary decision made during the design of this new system. In an effort to mimic the midline location of the central nervous system in biology, the pacemaker was placed in the middle of the design space from which the creature was built. Thus action potential waves could propagate out equally in all directions and were not biased in any particular direction of travel. In order to test the effect of this arbitrary choice, a treatment was also performed where the pacemaker was located at the center voxel of the roof of the $10 \times 10 \times 10$ design space – voxel number 955 (where indices increase from the bottom, left hand, nearest corner), as well as a treatment that placed the pacemaker in the top right corner – voxel 999.

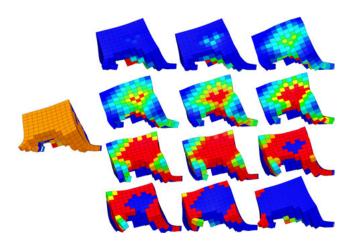

Figure 4: An action potential wave propagating across a mostly homogeneous surface. (left, single robot): The robot has a large patch of continuous conductive muscle on its back. In this pre-simulation state, cell colors signify the following: orange cells are conductive, blue cells are non-conductive; dark colors (blue or orange) signify muscle cells, while lighter colors (blue or orange) signify nonactuatable cell tissue; the red cell at the bottom is the robot's pacemaker cell. (right, 3 × 4 grid of robots): A progression over time (left to right, top to bottom) shows the wavelike propagation of the action potential phases (color meanings are described in Fig. 3). Note how the action potential emerges from the center, stimulated by the wave propagating out through the conductive tissue from the pacemaker below it. Following the light blue depolarization, the yellow and red phases show the longer lag of the refractory period, following in exactly the same pattern made by the leading edge of the action potential wave. As the wave fully passes, the cells return to their dark resting state and are thus able to spike again with a new action potential when the next wave comes.

As shown in Fig 6, the placement of this pacemaker significantly affects performance. While a central location (baseline treatment) shows significant advantages compared to the top-center and top-corner pacemaker locations ($p=4.91\times10^{-11}$ and 7.16×10^{-16} , respectively), a statistically significant difference is also demonstrated between the two less-different treatments: the top-center location outperformed the top-corner location ($p=3.43\times10^{-4}$). These results show that the pacemaker location can have a clear effect on the evolved behaviors. Future work shall place the exact location under evolutionary optimization.

Speed of Pacemaker

Another implementation decision was the low-frequency pacemaker to allow for static gaits. The increased stability and robustness of static gaits is appealing, and this may allow better transferability to physical robots (Belter et al.,

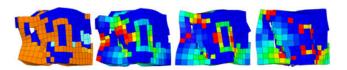

Figure 5: A more complex electrophysiological robot. (*left robot*): Contrary to Fig. 4, this creature shows complex patterning of the orange conductive tissue within the insulating blue tissue. (*right three robots*): As they unfold over time (left to right), the action potential waves in this robot produce a highly fractured, counter-intuitive actuation pattern that involves electrical signals flowing through long, sparse connective corridors and around corners (an explanation of the colors is provided in Figs. 3 and 4). The result is an interesting and unexpected behavioral pattern wherein the creature mashes and spins the left side of its body, which is separated from the larger, right side of its body by a large, oddly shaped internal cavity. Despite this bizarre behavior, it effectively locomotes. This behavior and others can be viewed on Youtube at: http://goo.gl/CvJp41.

2008). However, animals often employ dynamic gaits when there is an incentive for speed (as there is here). The tradeoff between these two is not known in this system. To examine this tradeoff, we compared three different treatments. First, the baseline treatment includes a pacemaker with the relatively slow pace of 40 beats per second (BPS). Since the baseline evaluation period is half a second, this results in 20 electrical pulses from the pacemaker per trial. A second treatment explores the increased potential for dynamic gaits at the maximum pacemaker speed of 80 BPS (the limit is due to the fixed length of the refractory period). In this faster treatment, each individual cell contracts at the same rate as before, but the pacemaker is now exciting cells as soon as their refractory period ends, instead of waiting (the length of an additional actuation cycle) before sending another pulse into the system. This system uses twice the amount of energy, producing 40 action potential waves in the same half second. In a third treatment, the faster paced (80 BPS) pacemaker is evaluated for half its normal time length, resulting in 20 beats per evaluation. This treatment allows a fair comparison of pacemakers in terms of distance traveled per "beat", rather than per unit time.

Unsurprisingly, the faster pacemaker evaluated for the full half second outperforms both the slower pacemaker evaluated for the same time period and the faster pacemaker evaluated for the shorter evaluation time ($p < 10^{-16}$ for both, Fig. 7). Interestingly, the frequency of the pacemaker has no significant effect on the distance traveled (p = 0.51 at generation 1000), suggesting that any disparity between the faster and slower gaits was not realized in simulation (with the number of beats held constant). Testing this result in the transfer to physical robots is a subject for future work.

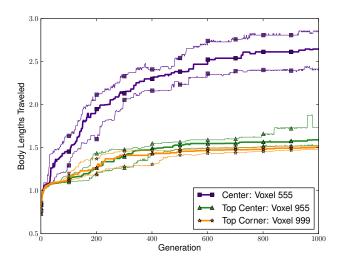

Figure 6: The effect of the placement of the central pattern generator (CPG) on the evolved speed. In one treatment, the CPG is placed at the top corner of the $10\times 10\times 10$ design space (voxel 999). This treatment performs slightly, but significantly ($p=3.43\times 10^{-4}$), better than another treatment that places the CPG at the center of the top plane of the bounding box (voxel 955). Outperforming both of these ($p<4.91\times 10^{-11}$) is the baseline treatment in which the CPG is always placed as close to the center of the bounding box as possible.

Touch Sensors

Another implementation decision was the use of pacemakers as the primary drivers of the system. While pacemakers, also known as central pattern generators, are biologically motivated [Ijspeert et al. (2007)], we could instead ask evolution to generate its own cadence. To provide an alternative to the pacemaker, we tested a treatment with touch sensors in lieu of a steady internal signal.

The touch sensors, like the pacemaker, are capable of producing an electrical signal. However, they do so in response to contact with the ground, rather than in a regular rhythm. In this treatment, all conductive cells have this touch-sensing ability and produce an action potential when in contact with the ground if not in the refractory period. Thus waves of action potentials propagate outwards from the touch sensors only when they are both in contact with the ground and fully recovered from their prior depolarization.

Thus, the upper bound on the number of action potentials that the touch sensors could produce is that of an 80 BPS pacemaker (the 80 BPS pacemaker fires again as soon as exiting the refractory period, where the touch sensors do so only if also touching the ground at that time – the slower 40 BPS pacemaker waits the length of one cycle before firing again). To reach this upper bound, touch sensors would have to be touching the ground exactly at the time when they com-

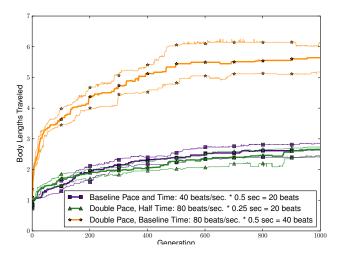

Figure 7: The effect of faster pacemakers (CPGs). It is not surprising that a faster CPG (80 beats per second) travels farther when evaluated for longer, or when compared to a slower CPG ($p < 10^{-16}$). However, when the the comparison is made according to distance per beat (half time/full speed against half speed/full time – both producing a total of 20 beats) there is no difference in their performance at Generation 1000 (p-value = 0.51), suggesting that CPG speed does not greatly affect evolved locomotion speed.

pleted their refractory period, and thus it is likely that this ceiling would not be reached in all cases. For a comparison, Fig. 8 shows the median distance traveled over evolutionary time plotted against that of the slower pacemaker (40 BPS) and the faster pacemaker (80 BPS) described above, and evaluated for the baseline half-second evaluation time. It is not surprising that the slower pacemaker falls behind the pack here, as it is handicapped by a throttle on its only source of action potentials compared to the faster pacemaker and the touch sensors ($p < 10^{-16}$). The tighter race is between the touch sensor and the faster pacemaker. In the early stages (< 150 generations), the robots with touch sensors significantly outperform robots with a pacemaker. However, in the later stages of evolutionary optimization, the touch sensor treatment shows modest gains compared to the continued innovation of the pacemaker treatment, with the pacemaker treatment significantly outperforming it at the end of the run $(p = 1.27 \times 10^{-7})$. The relatively low level of improvement in the touch sensor treatment in the later stages of evolution may suggest the premature convergence on local optima. The multiple points of origin for action potential waves, and thus wave collisions, may have also had an effect. An additional issue that could have hindered performance in this treatment is the upward propagation of signals from touch sensors on the ground, versus outwards expanding waves from the center of the organism.

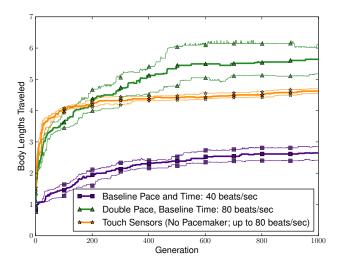

Figure 8: The performance of touch sensors vs. central pattern generators. The touch sensor treatment produces an expected number of beats with the upper bound set by the faster (80 beat/sec) CPG. Despite early evolvability leading to a statistically significant advantage in the first 150 generations, in later generations the touch sensor setup is unable to produce creatures that travel as far as the faster CPG setup $(p=1.27\times 10^{-7} {\rm \ at\ Gen.\ 1000})$. Artificially throttled, the slow CPG is unable to compete with either $(p<10^{-16})$.

Expansion/Contraction Cycle

In the soft robot evolution system described by Cheney et al. (2013), regular, quickly repeating, and coupled out-of-phase sinusoidal action cycles defined the expansion and contraction of cells. In this model, which does not feature the same complimentary muscle types, the question of actuation cycle is not entirely clear. In an attempt to explore this, here we test the effectiveness of contraction-then-expansion phase cycles against expansion-then-contraction cycles (Fig. 9). These treatments take place on the baseline (slow) pacemaker setup, as to not allow continuous and quickly repeating expansion/contraction cycles, but rather to have a break between actuations. Despite the same number of beats (and thus the same amount of overall expansion and contraction) in both setups, the contraction-then-expansion setup performs significantly better $(p = 1.94 \times 10^{-3})$. While the reason for this difference is not entirely clear, it may be due, in part, to a larger continuous expansion period from the trough of the sine wave to its peak (continuous expansion from minimum to maximum size) in the contraction-then-expansion treatment. In contrast, the expansion-then-contraction setup includes a full-cycle length pause in the middle of its expansionary period. This explanation would suggest that more locomotion tends to come from pushing than pulling, which is in line with our observations from viewing videos of the evolved behaviors.

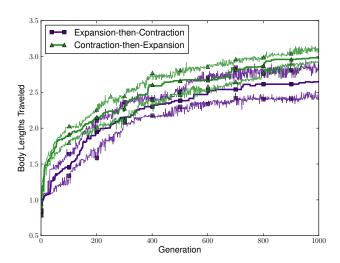

Figure 9: Unlike the regularly occurring actuation cycles of Cheney et al. (2013), the electrophysiological actuations in this paper do not have a necessary order: either expansion or contraction can occur first. It turns out that performance is significantly higher when muscles contract first and then expand, rather than vice versa $(p = 1.94 \times 10^{-3})$.

Discussion

This work reduces the separation between bodies and brains in research into embodied cognition. We did so by embedding the control systems into the physical simulation of the robot's morphology. Perhaps most interesting about this work is that the complex and interesting behaviors are the direct result of the morphology of the creatures, as the control is woven directly into the structure of the organisms. In this work the size of the creatures was limited for computational reasons, but in future work we plan to explore larger design spaces. We also plan to test different ways of implementing electrophysiological robots and to challenge them to perform more difficult tasks.

Conclusion

We have introduced electrophysiological robots, which are inspired by the electrical properties of cardiac tissue. The behavior of these robots is governed by electrical signals flowing though the evolved cells of soft robots. We described these robots and how they are evolved, including the evolution of interesting behaviors, despite the added challenge of physically embedded control structures. We also provided an initial experimental investigation into different implementation decisions, such as alternatives for sensing, actuation, and central pattern generator locations. We believe that this paper provides a first step towards removing the gulf between brains and bodies to encourage further research into physically realistic embodied cognition.

A model-based framework to investigate *morphological computation* in *muscular hydrostats* and to design soft robotic arms

Vito Cacucciolo, Matteo Cianchetti and Cecilia Laschi The BioRobotics Institute, Scuola Superiore Sant'Anna, Pisa, Italy { v.cacucciolo, m.cianchetti, c.laschi } @sssup.it

Extended Abstract

Soft Robotics is basically intended as building robots with highly compliant materials, but it is indeed more. Soft robots can safely interact with humans and with the environment and be able to adapt to different situations. These characteristics, combined with cheap materials and simple fabrication, candidate them to lead the next robotics revolution, when robots will massively move from the highly controlled industrial environments to the unpredictable real ones. As for the hardware, compliant materials such as silicones substitute stiff metals and rigid joints, following in under-actuated robots with virtually infinite number of degrees of freedom (DOF).

Controlling this extremely high dexterity using the same approach of hard robotics (i.e. a hierarchical top-down control) simply does not apply. On the contrary, a new vision of the coupling between body and intelligence has to be adopted. Instead of considering brain and morphology separated entities (with the first commanding and the second obeying) *morphological computation* (Pfeifer and Bongard, 2007) proposes a radically different standpoint. The nonlinearity and complexity of the body dynamics rather than problems are considered as part of the solution, as the produced richness of behaviors allow the morphology to carry part of the computational load, thus simplifying the required (central) control instead of complicating it.

This phenomenon is well observed in self-organization and embodiment of biological organisms, where characteristics like adaptability, robustness and agility are widely present without being explicitly controlled, and often without any (centralized) control. In the recent years many examples of embodiment in complex biological systems have been source of inspiration for robotics, ranging from cellular reproduction to the locomotion of more evolved animals like the salamander. A remarkable case where a central brain is present but still most of the sensory-motor control emerges from the body dynamics and the interaction with the environment is the octopus.

The octopus (octopus vulgaris) is an invertebrate sea animal showing high dexterity, variable stiffness and much

more complex behaviors than expected from its position in the evolutionary scale. Its body has virtually infinite DOF, resulting in a very high computational cost if pretended to be fully controlled by its central nervous system. It has been proved instead that its relatively simple brain mainly sends actuation patterns and most of the computation is performed by a combination of the peripheral nervous system, the dynamics of the compliant body and the interaction with the environment (Yekutieli et al., 2005). The result is an underactuated embodied system.

The element at the base of this system is the *muscular hydrostat*. It is an isovolumetric structure widely present in nature as a component of compliant animal bodies. Besides generating the forces for movements it also provides skeletal support, featuring extremely high dexterity and variable stiffness ability. It is composed by a combination of muscular fibers arranged in longitudinal, transverse and oblique directions (Fig. 1). The different activation patterns of these

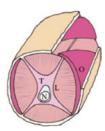

Figure 1: Longitudinal (L), transverse (T), oblique (O) muscular fibers and nerve cord (N) in muscular hydrostats.

muscular fibers generate all the basic movements performed by muscular hydrostats. The whole octopus body can indeed be considered as a complex system where the interaction above its elements and the environment lead to the emergence of the global behavior. The brain orients its outcome rather then controlling each intermediate step. Beyond being widely studied in biology, the octopus represents a rich source of inspiration for roboticists (Laschi et al., 2009), who want to reproduce its peculiar characteristics to build marine soft robots able to swim, manipulate, and move in

unstructured environments.

Understanding the principles underlying the behaviors of the octopus (and of other similar natural systems) is thus not only interesting from a biological standpoint but extremely useful for the design of a new generation of embodied soft robots. So far, this design has been mainly founded on biomimetics, meaning trying to reproduce biological structures in order to take advantage of their qualities. While this method has proven to be a powerful tool, it has two main shortcomings: the technological limits often encountered in reproducing biological structures (e.g., artificial muscles) and the challenge of applying embodiment principles to perform a defined task.

This reveals the need for a systematic design framework able to extract the basic principles of the embodied intelligence, transferring them into an artificial system while taking into account the technological limits and the (main) tasks to perform. In order to apply this *Design for Emergence* (i.e. shape the morphology so that the desired behaviors are likely to emerge) a modeling phase has to be included, where the complex characteristics of the system are synthesized and quantified and the technological constraints included.

In this work a lumped-parameters mathematical model of the nonlinear dynamics of a muscular hydrostat is proposed, inspired to the work of Yekutieli et al. (2005), where a similar model has been used to study the octopus reaching behavior. The presented model is realized as a complex network of masses and springs in order to reproduce the rich dynamics of the octopus arms (Fig. 2). Furthermore it is general, thus

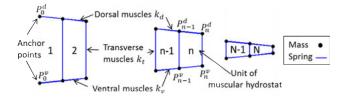

Figure 2: Scheme of the lumped-parameter arm model.

able to simulate a wide range of animal structures based on muscular hydrostats (e.g., octopus arm, elephant trunk) as well as, fittingly setting the parameters, soft robotic arms with muscle-like actuation (e.g., pneumatic, hydraulic).

Differently from other similar models, the equations of motion were obtained using an energy-based method (*Lagrangian mechanics*). The two main reasons are: have a set of equations where it is easy to add various constraints; energy and generalized coordinates provide a full description of the evolution of the system, the former at a global level, the latter at a local (*agent*) one. Constraints were applied to add the isovolumetric feature of muscular hydrostats and contacts (a novelty in these studies) to model the interaction with the environment (Fig. 3), opening to the investigation of grasping tasks and safe interaction with humans.

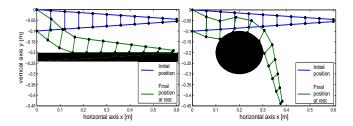

Figure 3: Soft arm free falling in contact with a hard plane (left) and sphere (right).

The proposed model is meant to be combined with evolutionary computation tools in a set-up for brain-body co-evolution (Lipson and Pollack, 2000): a genetic algorithm contemporary optimizing a neural controller (the brain) and the arm model parameters (the body), with the fitness mainly represented by the performance on an assigned task (e.g., reaching a point, grasping an object). Respect to other similar works the evolution is not from *tabula rasa*, as the design space, contemplating the different combinations of morphology and control, is extremely wide and with plenty of local minima. Thus, in order to simplify the genetic optimization process, bio-inspiration is used to focus the design space about biological systems well-suited for the desired tasks.

The aim of this set-up is twofold. First, the quantitative and task-related analysis of embodied intelligence and morphological computation in biological systems based on muscular hydrostats: thanks to the realized coupling the body parameters influence how the control is shaped by the genetic optimization and *vice versa*. Second, setting the model parameters to fit technological constraints (relative to a chosen actuation technology), the definition of a new framework for the Design for Emergence of soft robotic arms, where morphology and control are simultaneously optimized to reach the emergence of the desired global behaviors with the simplest software and hardware.

Evolution of Locomotion on a Physical Tensegrity Robot

Mark Khazanov¹, Jules Jocque¹, and John Rieffel¹

¹Computer Science Department, Union College, Schenectady NY 12308 rieffelj@union.edu

Abstract

Due to their high strength-to-weight ratio, robustness and deformability, tensegrity structures are an appealing platform for the emerging field of soft robotics, with applications ranging from search-and-rescue to field-deployable structures. Unfortunately, these properties also make tensegrities challenging to control through conventional means. In this paper we describe a novel means of vibration-based tensegrity actuation which allows for the manual control of a physical tensegrity robot in the plane as well as state-machine based target following. We demonstrate the evolution of effective gaits using only physical evaluations of the robot, and further demonstrate how a combination of the state-machine with the hill climber allows for the hands-off automation of the evolutionary process. We conclude with a description of how this can lead to a bootstrapping effect, with the potential to significantly accelerate and automate the physical evolution of our tensegrity robot.

Introduction

The term *tensegrity* describes a class of structures which are held together through *pre-stress* - a synergistic interplay of compressive and tensile forces. In engineering and architecture, tensegrity structures ranging in scale from camping tents to large stadium roofs are commonly built out of little more than compressive struts and tensile strings.

Because of their resilience and deformability, tensegrity structures are an appealing robotics platform. A tensegrity robot can alter its shape while preserving its structural stability merely by changing the resting length of its strings. Unfortunately, this property of *pre-stress* also adds a significant amount of dynamical complexity to the system. Because local changes to tension are redistributed throughout the structure, the system is dynamically coupled and highly resonant (Bohm et al., 2014) This dynamical complexity presents a challenge when trying to control tensegrities through conventional means.

Interestingly enough, the principle of tensegrity also exists throughout the biological world, at scales ranging from the musculoskeletal system of animals to the arrangements of the cellular cytoskeleton. The field of *morphological computation* (Paul, 2006; Pfeifer and Bongard, 2007) seeks

to explore how dynamical complexity can sometimes be advantageous in both biological and engineering realms, and how the intelligent behavior of systems can sometimes be *hard-wired* into their mechanics.

Tensegrities are therefore a compelling choice for exploring morphological computation. Broadly, our research explores the paradoxical notion that increasing a system's dynamical complexity can sometimes simplify its control. Specifically, we are interested in understanding how the dynamical coupling of tensegrity-based robots can be exploited as an advantage.

In this paper we demonstrate how the locomotion of a tensegrity robot can be controlled in the plane simply by changing the frequency of three vibrational motors. This steering behavior can then be combined with a finite state machine, allowing for autonomous target tracking. Moreover, we show how the motor frequencies can be optimized via evolutionary techniques, producing increasingly effective gaits. We believe that this is the first example of evolution on a physical tensegrity robot, and is the smallest and the fastest physical tensegrity robot in its class.

Understanding how to make dynamically complex tensegrities move will not only allow us not only to contribute to the emerging field of soft robotics, it will also add to our understanding of the biological systems which inspire us.

Tensegrity Robots

Conventionally, robotic systems are controlled by first dampening their dynamic and vibrational modes, and then controlling them in the quasi-static realm, in which analytical methods like inverse kinematics are capable of producing reliable controllers. The same is true of conventional approaches to the control of tensegrity structures. Skelton *et al.*, for instance, have been able to demonstrate both active vibration damping (2004) and open-loop control of simple structures (2004). Once this resonance is tamed, the robots are moved by changing the rest lengths of the tensile elements, for instance via servo motors (Paul et al., 2006, 2005)

Because of the challenge in building and controlling phys-

ical tensegrity robots, the majority of tensegrity robot research has occurred in simulation rather than reality (Aldrich et al., 2003; Paul et al., 2006; Graells Rovira and Mirats Tur, 2009; Iscen et al., 2013). One notable recent contribution is Caluwaerts *et al.*'s work (2013) on physical reservoir computing in a simulated tensegrity robot, in which they demonstrate learnable gaits produced by relatively simple central pattern generators (CPGs). More recently, Iscen *et al.* (2013) have evolved rolling gaits on a simulated tensegrity robot.

The case for physical evolution

While these simulated results are promising, the dynamics of tensegrities are complex enough that there is little hope of reliably breaching the *reality gap* (Jakobi et al., 1995) between simulated and actual dynamics. Not surprisingly, there are very few published examples of physically embodied tensegrity robots moving.

Shibata *et al.* (2009) and later Koizumi *et al.* (2012) built six-bar robots capable of motion. In each case, the controller was discovered manually. More relevant to our work, Paul *et al.* (2006) evolved gaits for a 3-bar tensegrity in simulation and then transferred the controller to a physical robot with only minor success.

Most of the tensegrity robot controllers described above operate at slow speeds relative to the structural dynamics, and can therefore be considered to be quasi-static – none of them truly take advantage of the inherent resonance of tensegrity structures. A notable recent exception is Zimmermann *et al.* (2011), who, like us, used vibration of a single motor as a basis for locomotion, however theirs is a modified (class-II) tensegrity, and only capable of forward motion.

The dynamics of tensegrity robots are sufficiently complex that there are no known purely analytical methods of generating gaits. As a consequence, every gait described above (with the exception of Paul's) was optimized through human trial-and-error, at the expense of considerable time and effort. This makes the domain particularly appealing for automated evolutionary approaches, which can remove human interaction (which can lead to error and bias in the search) from the discovery of effective gaits.

Acknowledging the limits of simulation and transferability however, limits us to *physical* rather than simulated evolution of tensegrity locomotion. This research then falls under the rubric of the Evolution of Physical Systems (sometimes called embodied evolution), following in the footsteps of Harvey *et al.* at Sussex (Harvey et al., 1997), Watson *et al.* (Watson et al., 1999), and more recently Zykov (2004) and Yosinksi (2011).

Unlike simulated evolution, the evolution of physical systems can be painstakingly slow, and requires considerable human interaction. Also unlike simulated evolution, however, our evolved solutions are, by fiat, guaranteed to work in the real world. As Rodney Brooks claimed, "the world is

its own best model" (1990).

A Robot Designed to Resonate

The motivation for our work lies in striving to exploit, rather than suppress, this inherent dynamical complexity as an advantage – making tensegrities move by vibrating, rather than suppressing their vibrations. Exploring these ideas required building a physical tensegrity robot.

Our ambition was to design a small tensegrity that was powered by vibration alone, robust enough to withstand prolonged testing and easy to manufacture and repair. The resulting design, based upon a canonical six-bar tensegrity shape, is shown in Figure 1. The geometry is defined by six equal length composite struts which are connected to each other via 24 identical helical springs, with four springs emanating from each strut end. Our prior work Khazanov et al. (2013) describes the design choices of the robot in more detail.

The robot is actuated with three independent vibrational motors capable of operating between 100 and 260 Hz. Each motor was mounted on a separate strut (leaving three of the six struts empty). Each motor is independently controlled by an off-board USB motor controller connected to a host computer. Very thin wires were used to tether the motors to the controllers, allowing for a minimal amount of interference through drag. Enough tether wire was used to enable a significant amount of twisting (caused by rotation of the tensegrity) before the need to manually unwind the tether.

The motion of the tensegrity robot could then be determined simply by independently varying the three motor frequencies. An analysis of the complexity of the ensuing dynamics can be found in our earlier work Khazanov et al. (2013).

The sections below describe various approaches to finding motor frequency sets capable of producing interesting locomotive gaits on our designed robot.

Setup

In order to evaluate gaits, the robot was placed on a 91x61 cm table (Figure 2) with a removable cork-board sheet as the surface. This material was chosen in order to provide enough friction for the tensegrity to move freely, while also allowing for it to grasp the surface. Wooden borders surrounded the testing environment to guard the tensegrity from falling during trials.

As illustrated by Figure 3, the process of distance measure was automated using an overhead USB camera connected to the control computer. The location of the tensegrity in a frame was determined by subtracting the image of an "empty" arena from an image containing the robot and then finding the centroid of the remaining pixels. The tether is visible in some frames, but has a negligible impact upon positional measurements. Distance could then be calculated by comparing the pre- and post-evaluation locations. The

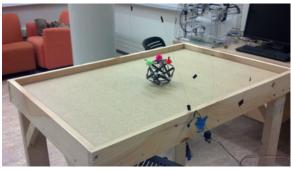

Figure 2: Left: The testing arena was a 91x61 cm table with a cork-board floor and raised wooden walls. The tensegrity robot was tethered to the control computer using thin wires. Right: A closeup of the tensegrity with the colored tracking markers. The yellow ball in the distance is the object used for target pursuit.

Figure 1: Our tensegrity robot is actuated by three independent pager motors mounted directly to the struts. Each motor is connected to an off-board USB motor controller with a very thin wire. (Photo by Steven Stangle)

arena was large enough that multiple evaluations could often be performed before manually returning the robot to the center of the arena.

Evolution of Motion

Using this setup, we then used a series of approaches to discover effective and interesting locomotive gaits for the robot. In each approach, the behavior of the robot was determined entirely by a "genotype" or frequency set, consisting of three motor voltages corresponding to frequencies for the three vibrational motors on the robot.

Hand Selected Gaits

The first step in our process was to use an interactive process to discover interesting gaits via human trial and error. A simple python-based user interface was set up allowing an operator to vary motor voltages while observing the behavior of the robot. Three particularly interesting gaits were discovered: one which produced linear "forward" motion

(the robot has no pre-defined front or back), one which rotated the robot clockwise, and one which rotated the robot counter-clockwise.

We could then manually switch between these three frequency sets in order to "steer" the robot around the arena (Khazanov et al., 2013). A video of this behavior can be found on our web page (http://cs.union.edu/~rieffelj/videos.html)

Target Pursuit in the 2-D plane

We then implemented a finite state machine which incorporated the three gaits described above in order to achieve fully automated target tracking.

To begin, we developed a machine vision algorithm, written in OpenCV, capable of using the overhead USB camera to detect the tensegrity's orientation on the plane. To do this we placed uniquely colored tracking markers on the three top-most strut ends. Using simple color detection, our algorithm could then detect each marker, and subsequently compute their center of mass along with the relative vector between the center and each colored marker. The lower row of images in Figure 3 illustrate this. The pink ball represents the "rear" of the robot - meaning that the vector from the robot's center of mass toward the front points in the opposite direction – as illustrated by the short line radiating from the center of mass.

A yellow target marker was then placed in the arena, and a steering angle calculated as the difference between the "forward" vector (the short line in Figure 3) and the vector to the target (the longer line in Figure 3). As illustrated by Figure 4 this steering angle, along with the robot's distance to the target, was then used as input into a simple four-state finite state machine. When the target was in front of the robot $(-30^{\circ} > steeringAngle < 30^{\circ})$, the forward gait was used. When the target was to the right $(30^{\circ} > steeringAngle > 180^{\circ})$, the clockwise gait was used, and when the target was to the left $(-30^{\circ} < steeringAngle < -180^{\circ})$, the counterclockwise gait was used.

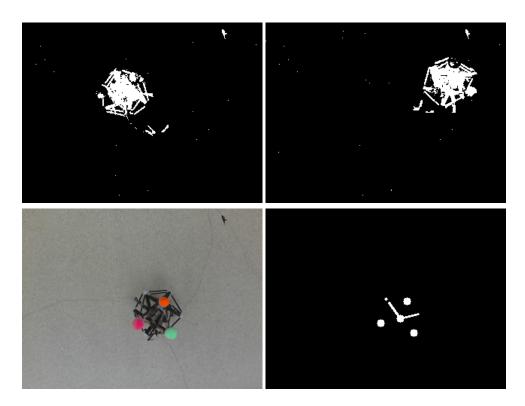

Figure 3: Using images produced by an overhead camera, distance traveled could be determined by measuring the difference in the center of mass between initial (top left) and final (top right) frames. Using colored markers (bottom left), we were then able to use machine vision to calculate the robot's orientation (bottom right). The short line indicates the "forward" vector or the robot. The longer line shows the vector to the target.

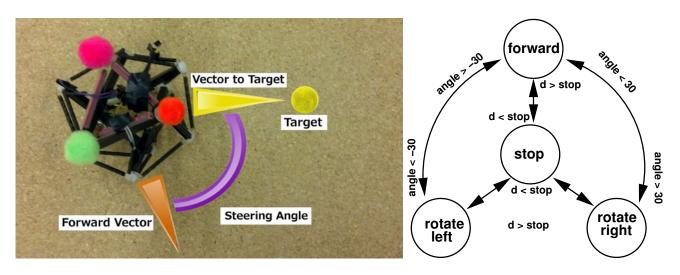

Figure 4: Left: Using machine vision code written in OpenCV, we were able to detect the location of colored markers on the tensegrity and use this information to determine the robot's absolute orientation, as well as relative angle to the target object. Right: this steering angle was then used as input into a finite state machine which switched between forward and rotational gaits.

When the machine vision algorithm, the state machine, and the hand-selected gaits were combined in this manner, it allowed for quite effective target tracking in the 2D plane. A video on our web page shows this target tracking behavior in action.

Evolving Gaits with Human Interaction

Our next step was to automate the trial-and error process used to select effective forward-moving gaits by implementing a simple population-based hill climber. The aim was to find forward moving gaits which outperformed those produced by trial and error in the section above.

The genotype, consisting of three motor frequencies, is insufficiently complex to justify more complex search techniques. (In the future we will be moving toward more evolvable representations and controllers, such as Artificial Neural Networks).

To perform the search we used a population size of 10 individuals, with 50% elitism (keeping the best half of the population between generations). In order to account for the noisiness of real-world evaluation, during successive generations all members of the population were evaluated, including those that had been carried over from prior populations.

Evaluation of a motor frequency set genotype was performed by measuring linear distance traveled by the tensegrity over the course of 7 seconds. The distance was measured using the automated machine vision algorithm described above.

This evolutionary process produced results, but was incredibly time intensive, since human effort was required to manually reset the tensegrity back to the starting position in the arena between evaluations. This inspired us to consider a more hands-off approach.

Hands-free Evolution of Gaits

Combining the target-following state machine described in an earlier section with the hill climber described in the previous section allows for the hands-free evolution of gaits.

This is accomplished by using the state machine to steer the tensegrity back to the starting position after every evaluation. In effect, this was as simple as treating the starting position (always the center of the arena frame) as a virtual target for the state machine's steering vector calculation.

This hands-free evolution allowed a significant number of repeated trials without any human interference at all, and an overall reduction in total number of interactions during an evolutionary run. The following section provides a more quantitative and comparative analysis of interactions required between the two setups.

Nonetheless, the physical evolution of tensegrity robots is still time intensive (if less labor intensive). Figure 5 shows maximum fitness achieved over the course of 25 generations between two different evolutionary runs. The non-monotonically increasing nature of the search is due to the

fact that all members of the population were re-evaluated. Evaluation of tensegrity robots is an inherently noisy process because of a variety of complex interactions and sensitivities such as friction, motor phase and motor hysteresis. Our discussion below explores better ways to approach these issues.

Results and Discussion

The hands-on and hands-free approaches to evolution produced equivalent fitnesses over 25 generations, and we make no claims that one produces quantitatively better gaits than the other. Nor would one necessarily expect otherwise, since the only distinction between the two algorithms – how the robot returns to the starting location – has no bearing on fitness evaluations or the larger search technique.

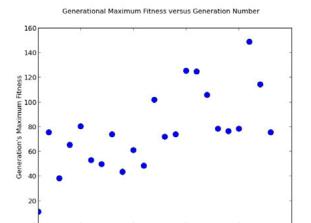

In both cases, since we re-evaluated the entire population each generation, and only used the latest fitness for the purposes of selection, there is not the typical monotonic increase in fitness found in most GAs. In the near term we are interested in more sophisticated measures of dealing with noisy fitness evaluation - for instance by evaluating every genotype multiple times and keeping track of a running average. The field of noisy evaluation provides some insight on the matter (Fitzpatrick and Grefenstette, 1988). Finding elegant solutions to this issue has bearings on the entire field of physical evolution.

Where our two approaches differ most is on the qualitative level. The hands-on approach requires, at a minimum, one human interaction every 7 seconds in order to return the robot to the start position, meaning a 25-generation run with population size 10 involves 250 such interactions. (We are reminded of anecdotes of Zykov *et al's* (2004) physical evolution of a massive 9kg pneumatically actuated Nonaped, which had to be moved 3m back to its starting position between trials)

In contrast to the hands-on approach, our hands-off approach at best requires 0 human interactions during a 25-generation run, because the robot is able to steer itself back to the starting position.

In practice, the number of interactions required in both approaches was higher, due to the inevitable wear-and-tear on the hardware caused by repeated trials, often manifesting itself in broken soldering at the wire connection points. A second phenomenon which required human intervention was the twisting of the tether caused by too many repeated turns in one direction. There was no significant difference in the number of repair-related interventions between the two algorithms.

Our choices of a very simple genetic encodings (three numbers) and a very simple algorithm (a hillclimber) are deliberate. Our aims have been to demonstrate the feasiblity of the physical evolution of tensegrity gaits, to produce effective gaits, and to introduce a novel method of reducing the amount of human interaction required for the evolution of

10 15 Generation Number

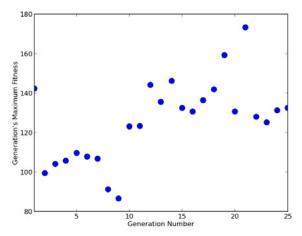

Figure 5: Fitness data from two consecutive 25-generations hands-free evolutionary runs of the tensegrity robot. Fitness measures are in cm of displacement over the course of a 7 second evaluation. The non-monotonically-increasing nature of the results is due to the re-evaluation of generational bests.

physical systems (by having the robot automatically reset itself between evaluations). More elaborate approaches might have distracted from these points. There are certainly more sophisticated algorithms for the Evolution of Physical Systems which we are eager to explore in the near future - especially the (1+1) restart-online adaptation algorithm (Bredeche et al., 2010; Montanier and Bredeche, 2011).

There are several modifications we could make at the hardware and software level to improve the robustness of the system and reduce the amount of intervention required. At the hardware level, we are exploring more sophisticated tether designs, such as those involving ring couplings. In the longer term, we are interested in transitioning to a completely wireless setup, with rechargeable batteries. On the software front, it would be relatively simple to keep track of the cumulative rotation of the robot over the course of evolution, and automatically "unwind" the tether when the sum crossed a threshold.

Toward Bootstrapping Evolution of Gaits

The most significant innovation to our algorithm lies ahead. We want to improve the hands-off method by more tightly coupling the state machine (used to return the robot to the starting location) with the learning which takes place in the evolutionary search for forward moving gaits. We envision a means by which, as newer faster forward gaits are discovered by the GA they could be used to "upgrade" the go-forward behavior of the state machine. This bootstrapping would in principle lead to increasingly shorter times between evaluations and therefore an overall increase in experimental throughput. We could even integrate aspects of novelty search (Lehman and Stanley, 2008).

The evolution of physical, rather than simulated systems,

poses many intriguing challenges, but offers the promise of finding novel solutions which immediately work in the real-world, thereby avoiding Jakobi's dreaded "reality gap", at the cost of real-world time and human interaction. Any innovation which is able to decrease these costs is therefore a valuable contribution to the field. After all, unlike simulations, one can't speed up the real world by buying a faster computer.

Conclusion

We have described a sequence of approaches to the discovery of novel vibration-based locomotive gaits in a physically embodied tensegrity robot. To the best of our knowledge, this is the first example of the physical evolution of tensegrity robot locomotion. Our discovered gaits operate fully in the dynamic range, and are successful largely because they are able to exploit, rather than suppress the inherent dynamical complexity of tensegrity structures. Broadly, these results lend further credence to the field of *morphological computation* and the notion that dynamical complexity in both living and engineered systems can sometimes be an advantage – minimizing the overall cost of control by "outsourcing" intelligence directly into the mechanics of a structure.

Abstract

We apply the concept of multicellular development to evolve bodies and controllers of soft-bodied animats, evaluated within simulated physics environment. Growth of an embryo is driven by a neural network-like controller in every cell. We show how, through an evolutionary process, this simple approach produces rich and complex morphologies of animats made of hundreds of cells and exhibiting life-like gaits without centralized control. We discuss design decisions and issues that needed addressing to make evolution of moving bodies possible and investigate how some of these decisions impact quality of obtained solutions. We then show how the system allows us to evolve animats that optimize both for distance and the use of actuating material. Finally, we demonstrate how it can be used to evolve developmentally plastic individuals, whose genomes encode more than one phenotype, each adapted to a different type of environment.

Introduction

The possibility of harnessing evolvability and scalability of biological development in silico has long generated considerable interest in the field of artificial life. The diversity of multicellular forms produced by natural evolution is breathtaking and so is evolution's effectiveness in an endless struggle to tweak and adjust existing forms in response to continuously changing environment. The central role of development has been recognized already at the times Theory of Evolution was originally formulated, while nowadays we also understand that it is owing to the development that structures consisting of trillions of cells can be encoded in genomes of informational content of merely millions of bits. It is thus only natural that the field of evolutionary computation attempts to tap into some of development's potential as a way of overcoming limited scalability of direct genetic encodings (see, e.g., Cheney et al., 2013, for a recent comparison in the relevant domain).

Historically, artificial development models have been classified into two broad approaches: grammatical and cell chemistry based (Stanley and Miikkulainen, 2003). The former use high level, algorithmic abstractions of development, while the latter explicitly simulate interactions of larger numbers of independent cells. When it comes to

body-controller coevolution of simulated animats, we think it would be fair to say that grammatical approaches (such as used in Sims, 1994; Lipson and Pollack, 2000; Komosinski and Ulatowski, 1999; Pilat et al., 2012) and other high level abstractions of development (such as CPPN based, Cheney et al., 2013; Auerbach and Bongard, 2012) have been immensely successful in producing diverse and life-like animat morphologies, of which many have become staples of the artificial life field. The lower level, fine-grained developmental approaches, where morphology emerges through self assembly, have also met with considerable interest and the capability of such systems to evolve complex shapes or display organized behaviors have been well investigated (see Doursat et al., 2013, for a recent review). Yet, when it comes to evolving moving animats, cell chemistry approaches did not seem to have met with as much interest (although see Schramm et al., 2011; Joachimczak et al., 2013; Bongard and Pfeifer, 2003; Meng et al., 2011; Kowaliw et al., 2004, for some notable exceptions). Certainly, a big factor for the limited success of cell chemistry approaches in this domain are their much higher computational costs. After all, ability to define whole body parts algorithmically, e.g., through parameters of geometric primitives, is much more efficient than assembling them from a set of cells, both computationally and from the point of view of reduced search space.

Nonetheless, despite their higher computational costs, we believe that approaches that embody the very ideas of artificial life in the form of self organizing, decentralized assembly deserve further studies and in particular, attempts to scale them from what we would consider a proof of concept level (few dozens of cells) to producing useful and diverse designs consisting of hundreds and thousands of cells.

The core ideas behind the approach presented in this work are not new: it can be considered a generic, cell-chemistry system, with cellular behavior driven by a neural network-like controller in every cell (see, e.g., Roggen and Federici, 2004 for another example), whereas the method for creating elastic animat bodies from multicellular structures has been previously explored by the first author (Joachimczak et al., 2013). However, since the system employed previously was complex and computationally heavy, scaling it up

beyond a few dozens of cells or applying to more complex tasks proved difficult. In this work we have thus attempted to refine and distill core ideas into a much simpler system and demonstrate how a relatively straightforward, physics based multicellular development allows to evolve complex and diverse morphologies of virtual animats built of hundreds of cells and exhibiting life-like gaits.

The model

The main computational cost of the approach we used previously to evolve multicellular animats was related to the model of gene regulatory network (GRN) in which product concentrations would change in a continuous manner and which would be encoded in DNA-inspired genomes of arbitrary length. Although such GRNs were demonstrated to be quite evolvable (Nicolau et al., 2010; Cussat-Blanc et al., 2012; Joachimczak and Wróbel, 2010), frequent network updates and dense topologies resulting from this type of genetic encoding incurred high computational costs. To allow for evolution of more complex animats, we reapproached the problem with a simpler GRN model and refined physics, yet keeping the defining features of fine-grained, artificial development, so that we could use the system to investigate evolution of development in a biologically relevant manner. Hence, the body and the controller of an animat are the product of (i) progressive assembly of a multicellular structure by subsequent cellular divisions; (ii) all cells share a common, GRN-like controller; (iii) yet perform independent decisions based on their local neighborhood and differing activities of their virtual genes. Animats are grown during developmental stage and evaluated during locomotion stage for their capability to produce gaits through expansion and contraction of body regions, a concept that has recently received increasing attention as physical implementations of such robots have become possible (Shepherd et al., 2011; Hiller and Lipson, 2010).

In the following sections we provide description of the model and design choices, although given short space, limited to the essential aspects of the approach.

Development

Developmental process begins with a single cell and proceeds through subsequent cellular divisions. Cells are controlled by a simple abstraction of artificial GRN in the form of a recurrent neural network in which, to allow for richer regulatory logic, nodes can use different activation functions (from a prespecified set). The behavior of a cell depends both on external signals received by its network and network's temporal state represented as activation of its nodes. Inputs to a cell represent external signals from environment (e.g., morphogens, bias) and outputs are used to interpret actions taken by the cell, such as division, death. We used a signed sigmoid as the default activation function, and limited the range of values on output nodes (even if the function type underwent mutation) to <-1,1>.

Physics of development Development takes place in a continuous 2-D space, where cells are represented as discs and undergo elastic collisions simulated with springs that connect them. Cell's physical state is defined by its position, its velocity, and orientation vector which determines the direction of division. Springs connect only the nearest neighbors and are determined dynamically, as the embryo grows. We use Delaunay triangulation to determine the connectivity between cells and then remove links longer than 150% of cell's diameter (to allow for non-convex shapes). The resting length of a spring is equal to the sum of attached cells' radii. As this simple approach can however produce a disjoint structure (e.g., after cells in a central part of an elongated embryo die out), a spring between a pair of nodes is removed only when some other path between these two nodes can be found. Furthermore, having a lesser update cost, the underlying physics of development is iterated at a rate 10 times higher than the networks controlling cell behavior.

Morphogens Morphogen gradients have long been known to play a fundamental role in developmental process and, in particular, in establishing a basic body plan (Carroll et al., 2004). In the experiments discussed in this paper, we provided cells with direct and indirect positional information. The direct one was in the form of X and Y coordinate directly fed as input to a network. The indirect information would come in the form of virtual maternal morphogens at prespecified positions in the environment. Depending on an experiment, corresponding network inputs would report to a cell either morphogen's concentration (decreasing with distance) or a gradient (direction towards the source of this morphogen). Additionally, to allow for a simple form of cell to cell communication, cells have 2 "morphogen" outputs, whose activations are accessible to their cellular neighbors. Through a 2 corresponding inputs, each cell has access to an averaged value of activation of these outputs in its neighbors.

Cell division and death Whenever cell division occurs, a newly created cell receives a copy of original cell's network, including its state, that is current node activations. From then, any change in the patterns of network activities is the result of symmetry being broken owing to the differences in external signals perceived by each of the cells. Division and death (apoptosis) occur when the activation level of the network's node associated with respective function is found to be above a fixed threshold (0.8). The newly created cell is placed next to the original cell, in the direction determined by orientation vector of the original cell. Its angle is determined by the state of the associated output node at the time of division. As the mechanism controlling orientation and timing of cell division has a major influence on the range of morphologies that can be achieved through development, we discuss two approaches we investigated in the results section.

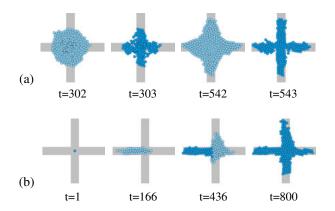

Figure 1: Example snapshots from development of 2 embryos (blue cells) evolved to produce cross shape, overlaid on the target to which embryos would be compared during evaluation (gray). (a) the system allowed for unconstrained cellular divisions whenever an associated output crossed a threshold, the final shape is a result of repeated subtractive process: apoptosis removing excess cells; (b) cell divisions were constrained to non occupied space, evolved shape is a result of an additive assembly. Brightly colored cells have their division signal above the threshold.

Termination of development To prevent trivial scenario in which cells divide in an uncontrolled manner until hard limit of embryo size is reached, we required development to self terminate by stopping both cellular divisions and deaths during last n steps of developmental stage. During evolution, individuals that would not fulfill this criterion would be penalized by having their fitness values divided by a penalty constant. Additionally, we added a limit on the total number of cells that can be created during development of an embryo to be no larger than 4 times the maximum of cells allowed at a time. We did so to limit the occurrence of rather unrealistic solutions we initially observed in which, despite the shape being stable, cells would be indefinitely created and destroyed.

Soft-bodied animat model

The morphology of an embryo in the final developmental step is used as a template for a soft-bodied animat that is then evaluated for its capability to produce gaits. The animat is represented in the physics engine as another springmass system, with point masses located at cell centers and springs forming a triangular mesh. Springs are assigned default resting lengths based on distances between cell centers at the end of developmental stage. Additionally, each triangular region has an equilibrium pressure (also determined at the end of development) and resists excessive compression or stretching. Two examples of transformation from a developed embryo into a soft-bodied animat can be seen in Fig. 4.

Finally, we chose to address a class of solutions that could emerge through developmental process that would be difficult to interpret physically and costly to simulate because of their requirement of increased accuracy to maintain stable behavior, namely solutions in which some of the body regions would have zero thickness. This could happen when a single line of cells would grow out from the main body during development, in which case it would be represented as a chain of point masses attached to the animat. We addressed this scenario by iteratively removing such cells at the end of developmental stage. A related case occurred if two larger body regions were found to be connected through a single cell or a chain of cells (a simplest example of such an individual would be 2 triangles sharing one vertex). We assigned the fitness value of 0 to such animats.

To avoid self penetration of animat bodies, masses representing cells would undergo elastic collisions with springs. Movement during locomotion stage was simulated using a custom soft-body engine built on top of Bullet Physics library. As physics simulation is the most time consuming part of individual's evaluation, we found it highly beneficial to employ a dynamic length of simulation step dt, which would have a larger default value but would decrease on demand, when high accelerations or node-spring collisions were detected.

Locomotion Control is achieved in a distributed manner: each cell independently controls the lengths of its attached springs. After development is finished and locomotion stage begins, network controllers in cells simply continue to function and communicate through morphogens as they did, however, their division/death outputs are now ignored, and the output responsible for actuation can increase or reduce resting lengths of springs attached to a given cell. The resting length of a spring is modified according to the activation of outputs in the two cells attached to the spring and equal to $L = (1 + A_{\text{max}}(s_1 + s_2))L_0$, where A_{max} is a global parameter representing the maximum amplitude of change from one cell ($A_{\text{max}} = 0.15$) and s_1 and s_2 are corresponding activations of each cell's actuation output. Just as during the developmental stage, for performance reasons, the frequency of updates of networks in cells continues to be an order of magnitude lower than that of the underlying physics. To avoid jerky movements that would result from potentially sudden changes in the resting lengths of springs after each network update, we modify the resting lengths progressively, in between subsequent network updates.

Genetic encoding and genetic algorithm

To encode and evolve networks controlling animats' cells we employed NEAT (neuroevolution of augmenting topologies Stanley and Miikkulainen, 2002), which can be considered one of the state of the art methods of evolving artificial neural networks. In the NEAT method, genomes are represented as a list of nodes with their associated type (in-

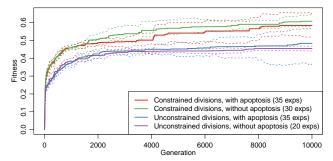

Figure 2: Comparing evolvability of target morphologies while using two different modes of cellular division with cellular death (apoptosis) either enabled or disabled. Solid curves show medians of best individuals in series of experiments of each type, dashed curves show bootstrapped 95% confidence intervals.

put, output, hidden), activation function (we allowed for sigmoidal, gaussian, step, linear, sine and abs functions) and a list of connections. The NEAT algorithm keeps track of innovations history and uses it to perform crossover between genomes. It also uses fitness sharing approach with the goal of preserving diversity and protecting new solutions before they have to compete with the rest of the population. We used population sizes of 300 and runs of 2000 generations (body-controller coevolution) or 10 000 generations (evolution of desired shapes). Initial population was created as a fully connected feed-forward network with a hidden layer and random weights.

Results

To verify the ability of the proposed approach to evolve structures made of hundreds of cells, we chose to first attempt evolving embryos that would be required to develop into a simple shape (such as a disc or a cross), using a fitness function that would reward similarity of the obtained morphology to the target shape. This allowed us to gain initial insight into how evolutionary process shapes development and to adjust physical constants so that development proceeds in a stable manner. Only then we have attempted coevolving morphologies and controllers for locomoting animats.

Evolving desired morphologies

To evolve embryos with desired shapes, we discretized target shapes into pixels and used a straightforward fitness function defined as $f=\frac{i-o}{c}$, where c was the count of pixels that a shape consisted of, i the count of the shape's pixels that were covered by the embryo at the end of developmental process and o was the count of pixels occupied by cells outside the target shape.

In our first attempt, similarly to the previous works (Joachimczak and Wróbel, 2012), we allowed cells to simply divide whenever activation of the output associated with

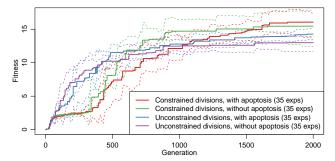

Figure 3: Comparing evolvability of animat gaits while using two different modes of cellular division with cellular death (apoptosis) either enabled or disabled. Solid curves show medians of best individuals in series of experiments of each type, dashed curves show bootstrapped 95% confidence intervals.

division crossed a threshold. Although we were able to obtain highly fit individuals for simple target shapes such as an ellipsoid or a cross, analysis of their developmental process revealed that it was rather simplistic: cells would tend to divide in synchrony at the maximum allowed frequency, with their orientation vectors hardly showing any organization or relevance to the target shape. Rather than a product of organized growth towards a desired shape, a good match of morphology to the target shape was found to be simply the result of apoptosis trimming excess cells after growth (Fig. 1a). As the developmental process in which there is little or no differentiation between cellular behavior did not seem as a good starting point for evolving complex animats, we pursued other approaches that could facilitate cells taking control over timing and directionality of their divisions.

Ultimately, we have introduced a simple modification to the division process: a cell would not divide in the direction that was already occupied by another cell (it could however divide if there was a small amount of space available, the physics would push obstructing cells to the sides). Assembling an embryo of a shape other than line of cells would now require active control over the direction and timing of cell division, thus enforcing emergence of differentiation in cellular behavior already at the very beginning of evolution. Another useful property of this mode of division is that due to the fact that nearby cells receive largely similar external signals, cells tend to grow off the main body in groups sharing similar orientation vectors, facilitating creation of animat's protrusions. Shapes obtained in this manner had on average similar quality compared to the unconstrained approach (when using cross target shape, of the 20 runs, 10 would produce a 4-armed shape, while remaining ones would result in 3- or 2-armed shapes), yet the developmental process would rely on a clearly more organized, progressive growth (Fig. 1b).

To quantitatively investigate the difference between the two approaches, we compared quality of solutions obtained in repeated evolutionary runs using both methods. Surprisingly, the most fit individuals of all the runs were obtained using unconstrained divisions, although the median quality of these solutions was found to be lower (Fig. 2, red and blue curves). Since we hypothesized that the main reason unconstrained divisions can produce high fitness solutions is the ability to selectively remove cells at the end of development, we have performed the same comparison rerunning evolution with apoptosis disabled. High quality solutions with unconstrained development became entirely absent, and the medians of fitness distributions of best individuals at the end of runs were clearly different and in favor of constrained development ($p < 3.01^{-9}$, Wilcoxon two-tailed rank test; green and violet curves in Fig. 2). We interpret it as a confirmation that allowing for unconstrained divisions and apoptosis makes evolution focus its search on high quality yet trivial and unlikely evolvable solutions, in which the activation of the output responsible for apoptosis is simply a direct function of cell's spatial location.

To see however if this observation carries from the evolution of directly specified morphologies to the evolution of soft-bodied animats, we have later performed an analogous set of experiments on the latter problem. The results do exhibit similar pattern (Fig. 3). Although when apoptosis was enabled, the observed higher median quality of solutions obtained in experiments using constrained division was not confirmed to be significantly different from unconstrained division (p = 0.09), the difference was significant when apoptosis was disabled ($p < 9.63^{-4}$). Furthermore, visual analysis of individuals obtained with unconstrained cellular divisions also suggests that even with apoptosis enabled, their shapes would tend to be simpler and more convex. This also explains why this mode of division produces higher fitness individuals during the first few hundreds generations: before the constrained developmental process evolves enough control over cellular divisions to produce useful morphologies, unconstrained development has already discovered many largely circular morphologies that can move. Yet, this bias for convexity makes it harder to discover more complex solutions later on.

All animats in the experiments discussed later in the paper were therefore evolved using constrained cellular divisions.

Evolving soft-bodied animats

We evolved individuals for their ability to produce gaits in a 2 dimensional environment with gravity, with fitness function corresponding to the distance traveled during the length of the locomotion stage. Evaluation would proceed by first developing an embryo during developmental stage, converting it to a soft-bodied animat and simulating its behavior during locomotion stage. Coevolving controllers with unconstrained morphologies posed however a set of additional challenges that needed to be addressed, so that the genetic algorithm would avoid certain local minima.

Figure 4: Examples of two developmental processes leading to creation of the animats seen in Fig. 5ab. The last frame of each sequence shows morphology after the embryo is converted into a soft-bodied animat. Figure videos: http://youtu.be/Q6XXohgPP4A, http://youtu.be/1c-V-ttMIZI

Fitness function In particular, the most straightforward approach of calculating displacement of individual's center of mass during locomotion stage was found to not work well and to be very deceptive for evolutionary search. The prime cause of that was the fact that physical environment of the locomotion phase differs from the developmental phase by the presence of gravity. Enabling gravity at the beginning of simulation thus causes animat to first compress under its own weight. If displacement of the center of mass was used as a fitness function, evolution was found to quickly exploit this by focusing evolutionary search on vertically elongated structures that collapse and produce horizontal displacement by bouncing of the ground in often spectacular, yet not particularly useful ways: clearly, it is easier to discover genomes that produce elongated, vertical morphologies than individuals that can coordinate their actuation well enough to produce some movement. An obvious solution of giving an animat a certain fixed time to equilibrate did not entirely solve the problem either, as the genetic algorithm turned out to be very successful in discovering vertical structures that can balance themselves for even long periods of time and start collapsing exactly after this fixed period of time. In the end, we addressed this problem twofold. Firstly, we enabled drag, proportional to the speed squared, to act on the nodes during equilibrating. This largely eliminated exploitation of physics with tall animats that reach very high speeds and forces when collapsing under gravity. Secondly, we would start actual evaluation of the motion only after the center of mass was determined to be immovable (within a precision of a set threshold) for a certain number of steps.

Guiding the exploration of the search space towards individuals capable of any locomotion was yet another problem that required special attention. As we wanted to avoid introducing bias on the search by using handcrafted seed individual, we attempted to start evolutionary process with simple randomized genomes. A random network is not however guaranteed to make the first cell divide at all, and even if it does so, the resulting morphology is not likely to display any actuation. This essentially means that an individual that does not even start divisions and a potentially promising morphology with pronounced appendages, but incapable of

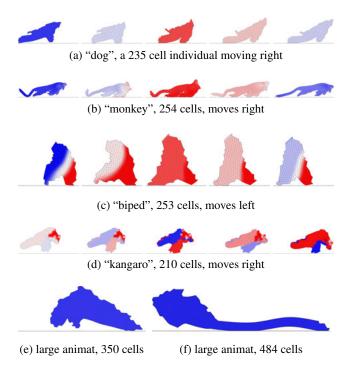

Figure 5: Motion snapshots of example obtained soft bodied animats. Colors show actuation: red - spring resting lengths are increased, blue - decreased, white - they are at their default, initial lengths. Figure videos: http://youtu.be/7y8HixKBO8g

actuation, would both have the same zero fitness assigned. To help search algorithm differentiate between these two cases, we have introduced these simple measures: genomes that would produce a valid multicellular embryo that terminates its development would receive a base fitness of 0.1. On top of that, a small reward (up to 0.1) would be added if the outputs controlling the resting length of springs would change their value during evaluation, proportionally to the amount of actuation. Only then, the reward corresponding to the actual displacement of animat's center of mass would be added on top of these basic rewards. This allowed to focus evolutionary search on individuals potentially capable of movement early on.

Evolved animats Having addressed the above issues, we found the system to produce surprisingly rich and efficient morphologies with relative ease, with almost all runs resulting in animats exhibiting gaits. A few examples of more interesting individuals are shown in Fig. 5 and the quality of their gaits can perhaps be best judged through the supplementary videos linked from the figure. Observed morphologies include clearly "2-legged" creatures (Fig. 5abc) as well as "1-legged" jumpers (Fig. 5d) or creatures with a "tail" (Fig. 5bf). Occasionally, circular, rolling individuals were also observed (albeit not shown here). Most importantly, it was common for the animats to evolve some forms of appendages to support their body and, in difference from

our previous work, appendages were not limited to a single cell or a few cells, but were clearly pronounced structures growing out of the main body and sometimes consisting of dozens of cells. Developmental process was also observed to be much more sophisticated than in our previous work, with differential growth rates in different body regions and occasional use of apoptosis (two examples of self assembling embryos are shown in Fig. 4). Patterns of cellular actuation would also often be differentiated spatially along the body, making cells contract and expand in a non trivially organized manner (e.g., Fig. 5d).

The animats shown in Fig. 5abcd were evolved with a 256 cells limit and were found to grow up to the higher end of allowed sizes. We expected this, given there was no cost of actuation and the fitness was an absolute measure of distance (i.e., not in relation to the body size), putting small individuals at disadvantage. We have also attempted evolving animats with a 1024 cell limit and have observed some larger solutions (Fig. 5ef), though the animats would often struggle to actuate under their increased weight and decrease in size as the evolution progressed, an issue we think is not so much a limitation of the system's scalability but rather requires readjusting physical constants that control the elasticities of springs and the amplitude of actuation.

Optimizing for material use Energy efficient gaits of biological animals are not only the result of work performed by actuators (muscles), but also body's ability to effectively convert kinetic energy into potential and elastic energy and vice versa, leading to motion patterns strikingly different from movements typically associated with robots, where movement is driven by actuators setting, e.g., precise angles of every joint. Creating animats out of elastic, compressible materials offers rich opportunities to invent efficient motion patterns that rely on converting kinetic energy into elastic energy and vice versa (as also recently explored in Cheney et al., 2013). As a trivial modification of the system we allowed one of the outputs to specify whether a cell is passive (activation < 0) or capable of actuation (activation >= 0). We have then modified the fitness function, so that it promotes reduced number of actuating cells. As a reward for reducing the use of actuators, the fitness component previously calculated directly based on the displacement of the center of mass, could now be increased up to twofold (though the maximum reward would only happen if a single cell was used for actuation). From the single preliminary experiment we performed, 5 of the 10 evolutionary runs resulted in animats that reduced their use of actuating material and relied on the elasticity of the rest of the body to produce motion patterns. Examples of their morphologies are shown in Fig. 6.

Evolution of developmentally plastic animats One of the main reasons behind the creation of a system that explicitly simulates multicellular development to evolve ani-

mat morphologies is to further our understanding of the relationship between development and evolution, by performing relevant evolutionary experiments *in silico*. In particular, we are interested in investigating the plasticity of animal development, both on the evolutionary level and of a single individual. The latter phenomenon, developmental plasticity, is understood as the capability of developmental process to take a different course and produce different phenotypes, each fine-tuned to a different state of environment they expect to find themselves (known as morphs, see e.g., Gilbert and Epel, 2008 for examples).

As a preliminary evaluation of the capability of the presented system to produce developmentally plastic animats, we have introduced a new type of external signal and a second type of environment, in which horizontal surface is replaced with a slope. Each individual was then evaluated twice, once in each of the environments. Whether an individual would be evaluated on a sloped or on a horizontal surface was then signaled by a value of 1 or 0 of the external signal, from the beginning of the developmental process. The fitness of every individual was then calculated as a square root of the product of fitnesses obtained in the two scenarios. The component fitness was calculated as in previously described experiments, with the exception that only animats moving right would receive a non zero fitness (as otherwise they would be rewarded for rolling down the slope). Although we were able to obtain some developmentally plastic animats which would produce 2 different phenotypes for each of the two environments, starting the evolutionary process became much more difficult, as finding individuals capable of moving up the slope even slightly without having previously invented some gait, was unlikely. Most of individuals in the early generations, even if capable of some minimal displacement on a flat surface, on a slope would simply collapse to a side, resulting in no displacement reward assigned and effectively random exploration of the genome space. Better results were obtained when we modified the fitness function so that individuals were first evolved to produce a gait on a horizontal surface, and then, since generation 500 until generation 2000, we progressively increased the angle of the slope until its target value. Fig. 7 shows an example of 2 individuals (their two morphs) obtained in this way.

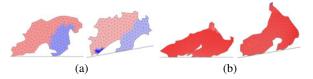

Figure 7: Two examples of developmentally plastic animats. Each animat in the pair is encoded by the same genome, which produces a different phenotype for a horizontal and sloped environment. Color indicates deviation of spring resting length at the time snapshots were taken. Figure videos, including development: http://youtu.be/lgbe2QbU0as

Conclusions and future work

In this work we have investigated the feasibility of applying fine-grained multicellular development to coevolve morphologies and controllers of virtual robots whose bodies consist of hundreds rather than dozens of independent components, i.e. cells. We did so by attempting to scale up the ideas introduced in our prior work, which however required us to reapproach the problem to facilitate growth of more complex structures. Ultimately, this allowed us to find out that a relatively simple developmental system employing neural networks as cell controllers, coupled with an improved approach to cellular division and simulated softbodied physics is all that is needed to enable evolution of much more complex and diverse forms.

We see the richness of morphologies and gaits that emerged in our experiments as an example of still largely untapped potential of multicellular development in the domain of morphology-controller coevolution. Naturally, when it comes to simply designing a robot, employing higher level abstractions of development, where components can be defined by geometric primitives instead of having to be assembled through a coordinated action of dozens of cells, would outperform our approach when it comes to computational complexity, especially if 3 dimensions were to be considered. Nonetheless, since this is not how the most evolvable system known so far, i.e., biological development works, we are willing to argue for the importance of pursuing evolvable cell-level abstractions of development, as a way to advance our understanding of development and its evolution. We thus plan to investigate further what aspects of the system facilitate evolvability and, in particular, lead to emergence of genotype-phenotype mappings in which relatively small changes in the genomes can lead to organized high level changes, such as enlargement or cloning of a whole body structure (see Doursat, 2009 for an example of such a system).

Finally, having shown the capability of the system to evolve developmentally plastic animats, we plan to investigate this aspect of development further, by analyzing how a single genotype-phenotype mapping diverges into two or more phenotypes (morphs) (see e.g., Palmer, 2012, for a recent discussion of the postulated hypotheses). Another form

of developmental plasticity that can be explored with this system is the capability of producing metamorphic individuals which, when triggered, can convert one phenotype into another, a phenomenon displayed by a wide variety of organisms that undergo staged life cycles in different environments (e.g., amphibians). From an engineering point of view, such artificial systems could be seen as a variant of evolutionary design, where instead of evolving single solution to the posed problem, genomes are evolved to encode a group or a continuum of solutions, each best adapted to a different variation of a given problem.

Adapting Morphology to Multiple Tasks in Evolved Virtual Creatures

Dan Lessin, Don Fussell, and Risto Miikkulainen

The University of Texas at Austin, Austin, TX 78712 dlessin@cs.utexas.edu

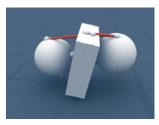

Abstract

The ESP method for evolving virtual creatures (Lessin et al., 2013) consisted of an encapsulation mechanism to preserve learned skills, a human-designed syllabus to build higherlevel skills by combining lower-level skills systematically, and a pandemonium mechanism to resolve conflicts between encapsulated skills in a single creature's brain. Previous work with ESP showed that it is possible to evolve much more complex behavior than before, even when fundamental morphology (i.e., skeletal segments and joints) was evolved only for the first skill. This paper introduces a more general form of ESP in which full morphological development can continue beyond the first skill, allowing creatures to adapt their morphology to multiple tasks. This extension increases the variety and quality of evolved creature results significantly, while maintaining the original ESP system's ability to incrementally develop complex behaviors from a sequence of simpler learning tasks. In the future, this method should make it possible to build EVCs with complex and believable behavior.

Introduction

Since their introduction two decades ago by Sims (1994), evolved virtual creatures (or EVCs; Figure 1) have had a significant impact on multiple fields, including graphics, evolutionary computation, artificial life, and robotics (Shim and Kim, 2003; Lehman and Stanley, 2011; Miconi, 2008; Lipson and Pollack, 2000). But despite their many incarnations in the intervening years, their behaviors have not grown more complex. Sims' original work demonstrated light following. This level of complexity has been approximately matched multiple times since (Miconi, 2008; Pilat and Jacob, 2010), but was never clearly exceeded until the ESP system of Lessin et al. (2013). ESP was shown to construct EVC behaviors approximately twice as complex as any seen before, measured as the number of discriminable behaviors in the creature's repertoire. Moreover, in principle there is no upper limit on behavioral complexity yet established within this new framework.

The ESP system is named for its three principal components-encapsulation, syllabus, and pandemonium-defined as follows:

(a) Initial locomoting creature.

(b) Heavy smashing arms.

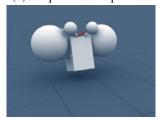

(c) Smashing flail arms.

(d) Jump with anti-tip limbs.

(e) Smashing tail, stabilizers.

(f) Jump with heavier body.

Figure 1: Adapting EVC morphology to multiple tasks. (a) A creature adapted for locomotion. From this creature, creatures (b) through (f) were evolved using the extended ESP method described in this paper. Each of them has developed a new technique (with corresponding morphological changes) for accomplishing an additional task—in this case, delivering a strike to the ground—while still maintaining the ability to perform the initial skill (locomotion) to prescribed levels. In the original ESP system, these secondary adaptations would have been impossible.

Once a new skill is learned, it can be encapsulated, which
preserves that ability and makes it easily accessible to future evolution.

- A human-designed syllabus is used to direct the sequential acquisition of these component skills toward the larger goal of achieving new, more complex behaviors, building up hierarchically from simpler ones.
- A *pandemonium*-like mechanism (Selfridge, 1958) is employed to resolve conflicts between competing encapsulated skills in the increasingly complex brain.

The initial ESP implementation did achieve its goal of breaking the behavioral-complexity barrier for EVCs. However, it applied only to a significantly restricted case—one in which some of the most important morphological changes (those to the creature's skeletal segments and joints) were prohibited after the first skill's evolution was complete. (Note, however, that muscle drives and photoreceptors—described below—could continue to be evolved throughout all evolutionary stages, even in the original system, since they can be added without disrupting existing abilities.)

This is a serious limitation. For example, what if a creature is evolved for an initial skill such as locomotion, then is asked to adapt to a largely orthogonal skill such as reaching up to a high target? That creature may or may not have the required morphological capacity for performing the second task, as determined only by the accidents of evolution.

This paper introduces a significantly extended version of ESP, in which a retesting and reconciliation scheme replaces previous absolute limitations on morphological evolution. Morphology is thus fully evolved to suit the requirements of more than just a single skill.

In the following sections, this new ESP implementation is described. The results demonstrate a significant increase in the useful variety and quality of evolved creatures, while the ability to incrementally develop complex behaviors from a sequence of simpler learning tasks is maintained.

The Underlying EVC Implementation

Both the ESP implementation of Lessin et al. (2013)—called *original ESP* in this paper—and its improvement that is presented in later sections—called *extended ESP*—were built on a reimplementation of Sims' original work (1994) that will be referred to as *the underlying EVC implementation*. That underlying EVC system—along with some important novel extensions—is described in the balance of this section, and a representative sample of its results is shown in Figure 2.

Evolutionary Algorithm

A conventional evolutionary algorithm is used, with elitism, fitness-proportionate selection, and rank selection (Mitchell, 1998). In addition, the most challenging tasks employ shaping (Urzelai et al., 1998; Gomez and Miikkulainen, 1997). Fitness is evaluated in a physically simulated virtual environment implemented with NVIDIA PhysX.

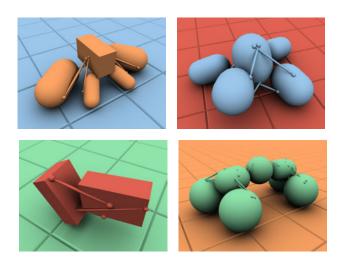

Figure 2: Typical results from the underlying EVC system. These examples were all evolved to complete a forward locomotion task—a common baseline result for EVCs.

Morphology

As in Sims' original work, creature morphology is described by a graph-based genotype, with graph nodes representing body segments, and graph edges representing joints between segments By starting at the root and traversing the graph's edges, the phenotype is expressed. Reflexive edges as well as multiple edges between the same node pair are allowed, making it possible to define recursive and repeated body substructures easily. In addition, as in Sims' work, reflection of body parts as well as body symmetry are made easily accessible to evolution, with only a single mutation required to produce each of them. In this implementation, all PhysX primitives are available for use as body segments: boxes, spheres, and capsules. Joints between segments may be of most of the types offered by PhysX, specifically: fixed, revolute, spherical, prismatic, and cylindrical. In contrast to the typical technique of separately evolving explicit joint limits, most limitations on joint movement are provided implicitly by creature structure through natural collisions between adjacent segments.

In addition to the typical segments and joints, the implementation of the underlying EVC system also evolves muscle drives and photoreceptors, as described below.

Muscles

In a break with traditional evolved virtual creature systems, which typically use forces exerted directly at joints, the underlying EVC system of this paper uses simulated muscles as actuators. Each muscle ((b) in Figure 3) is defined by two attachment points on adjacent segments, along with a maximum strength value. In simulation, the muscle is implemented as a spring, with muscle activation modifying the spring constant. In addition to acting as an effector, each muscle also produces a proprioceptive feedback signal based

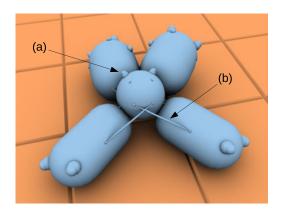

Figure 3: Photoreceptors (a) and muscles (b) bring sensing and actuation to creatures in the underlying EVC system. For both, function depends upon placement, so creature form develops meaningfully as capabilities are evolved.

on its current length. For each muscle, two nodes are added to the brain: one that accepts an input to set the muscle's activation, and another that makes the muscle's proprioceptive output signal available to the rest of the brain. Muscle drives benefit EVCs in several ways: they can be used even on creatures without joints; they only need to exist where they are useful, not at every degree of freedom of every joint; and they have the potential to embody some degree of control intelligence, with benefits for both aesthetics and the reduction of cognitive load (Lessin et al., 2014).

Photoreceptors

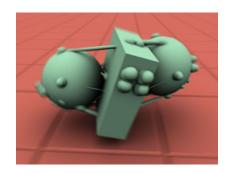

For tasks involving light sensing, creatures are allowed to develop simple photoreceptors ((a) in Figure 3), defined only by a direction from the center of their parent segment. This direction indicates a location on the creature's surface as well as an orientation for the receptor. The signal produced by the receptor is determined by light strength, distance, occlusion, and the difference between the direction to the light and the sensor's orientation. Multiple lights are allowed. For each photoreceptor in the body, a corresponding brain node is added which makes the receptor's output signal available to the rest of the brain.

Control

In a manner which is again very similar to that of Sims, creature control is provided by a brain composed of a set of nodes connected by wires (as in Figure 5a). Nodes receive varying numbers of input wires, and use their inputs to compute an output value (always in the range [0,1]) which may be sent to other wires. Signals originate from sensors in the body as well as certain types of internal brain nodes, travel through the network of internal nodes and wires, and ultimately control the operation of actuators (muscles) in the physically simulated body. For each step of physical simulation, control signals move one step through the brain.

In addition to the special node types for muscles and photoreceptors (described above) and for encapsulation (described in the *Encapsulation* subsection), the following node types are allowed: sinusoidal, complement, constant, scale, multiply, divide, sum, difference, derivative, threshold, switch, delay, and absolute difference.

The Original ESP System

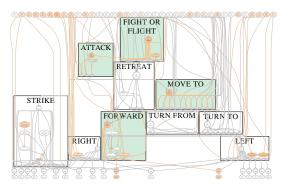

Figure 4: The body and brain of a creature evolved using the original ESP system. This creature achieved a level of behavioral complexity approximately double the state of the art. In addition to following a light, it was able to attack it or flee from it, as part of a hierarchical fight-or-flight behavior.

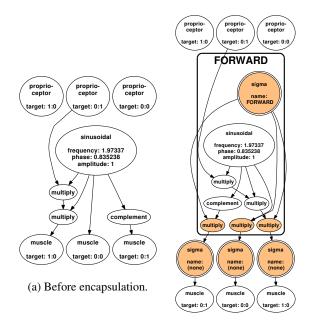

The original ESP system (Lessin et al., 2013) consists of three elements added to the underlying EVC system: encapsulation, syllabus, and pandemonium. In this section, each of these components is described in detail.¹

Encapsulation

The first important element of the ESP system is a mechanism to *encapsulate* newly learned skills (Figure 5). This element accomplishes two important goals: It ensures that previously learned skills (and the body components on which they rely) are preserved, and it makes these skills easily accessible to future evolutionary development.

Figure 5a depicts a brain evolved for forward locomotion, and Figure 5b shows the result of encapsulating it. First, the nodes that compute the old skill have been preserved and

¹For a video overview, see: http://youtu.be/dRLNnJlT8rY

(b) After encapsulation (with new nodes shaded).

Figure 5: Encapsulation. The automated encapsulation of an evolved skill—in this case, forward locomotion—ensures that it will persist throughout future evolution, while also allowing it to be easily activated as a unit by future skills.

locked (meaning that they have been marked to disallow any changes by future evolution). Second, a new *multiply* node has been inserted into every output wire leaving the encapsulated skill. The internals of the skill will continue to function as before, always trying to perform their forward locomotion task, but now, a second signal sent to each new multiply node will modify those outgoing forward-locomotion control signals, scaling them by a number in [0,1]. Third, a single controlling node (called a *sigma node* for its function as a summation of zero or more inputs) is added, which sends its output to all of the new multiply nodes. So for each signal s_i leaving a node in the FORWARD LOCOMOTION skill (such as the *complement* node), the new signal after encapsulation (s_i') is computed as $s_i' = \sigma s_i$ where σ is the output of the controlling sigma node.

Now, with encapsulation complete, the entire forward locomotion skill can be activated and deactivated as a unit by using the controlling sigma node just as if it were a single muscle in the creature's body. (Incidentally, note that this brain's actual muscle nodes have been hidden behind additional sigma nodes to allow future evolution to share control over them when appropriate.)

With the ability to preserve completed skills for easy future access, the next issue is how they may be acquired in sequence to achieve a larger learning objective.

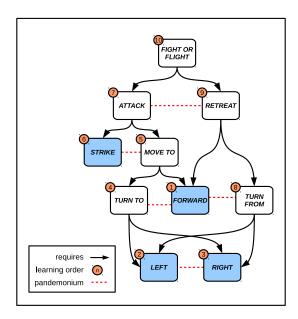

Figure 6: An example syllabus as a graph. Graph nodes represent individual subskills to be learned, directed edges indicate dependency between subskills, and the numbering indicates a proposed learning order that satisfies the dependency requirements. Pandemonium relationships are indicated by dashed red lines. The shaded nodes (called *leaf nodes*) affect only the body, rather than other nodes, and constitute the focus of the extended ESP system discussed in this paper.

Syllabus

While it is certainly possible for human students to learn a complicated topic independently, even advanced learners would be expected to develop further and with greater ease with the benefit of an expert-designed syllabus. The syllabus acts as a sequence of landmarks through the space of possible solutions, decomposing the larger learning task into a succession of more manageable steps between these way-points.

In the ESP system, the *syllabus* consists of an ordered sequence of fitness goals used to reach the ultimate, larger goal. This collection of intermediate goals (each one defined by a fitness function) is designed by a human expert with the aim of making attainable goals more reliably learnable, and bringing previously unattained goals within reach.

For example, assume that you want to evolve a virtual creature with some of the behavioral complexity demonstrated in an internet cat video.² Rather than simply drifting smoothly toward a target, this creature might run to the target, then strike it, and perhaps even run away if the target is perceived as threatening. Without a syllabus, a single fitness test evaluating such a complex collection of skills might be constructed, but evolutionary progress would be unlikely.

²E.g.: "THE BEST CAT VIDEO YOU'LL EVER SEE" [sic], http://youtu.be/20mrEtabOLM

Consider, instead, how this complex behavioral goal could be broken down into an ordered sequence of smaller learning tasks. The clearly achievable goal of locomotion will be the first target. The ability to turn left and the ability to turn right are of a similarly manageable difficulty, and will be attempted next. Then, with left and right turns mastered, and the ability to develop photoreceptors, it is relatively straightforward to maintain orientation toward a light source. And with the ability to face a light and the ability to move forward, navigating to that light might be a similarly achievable goal. Proceeding in this manner, a knowledgeable human designer might produce a sequence of subskills to be learned. Each subskill would be attainable with basic EVC methods, and earlier subskills would serve to make later skills easier to learn.

This information may be conveniently summarized in a graph, encompassing subskills to be learned, dependency between subskills, learning order, and pandemonium, as seen in Figure 6. In fact, the syllabus in this figure was used by Lessin et al. (2013) to produce the creature illustrated in Figure 4. This creature achieved a level of behavioral complexity approximately double the state of the art for evolved virtual creatures at that time. More specifically, not only was it able to move to a light target, as previous creatures had done, but also strike the target upon reaching it, and flee from the target when it became dangerous, doubling the complexity of behaviors in prior work.

At this point, a complex skill can be broken into smaller subskills, and those subskills can be cumulatively acquired, but a potential problem still remains: How are competing signals from the multiple sub-brains within a single creature resolved?

Pandemonium

Consider the following example based on the syllabus graph of Figure 6. A creature evolved through this syllabus will ultimately have parts of its brain devoted to both left and right turns. But it seems unlikely that both of these abilities should ever be used at the same time. So the syllabus designer might place the left and right-turn skills in a *pandemonium* relationship with each other (Selfridge, 1958), meaning that whichever one is most active at any given moment will be allowed to send its output at full strength, and the other will have its output entirely suppressed. Under a system like this, sub-brains within the creature can compete for overall control, with little risk of sabotaging the usefulness of the entire brain's function. In Figure 6, a full set of pandemonium relationships is indicated by red dashed lines between subskill nodes.

Although this original ESP system achieved more complex behavior than before, body segments and joints could not continue to adapt beyond the first skill's completion. In the next section, a more general form of the ESP system is described that makes this possible.

The Extended ESP System: Adapting Morphology to Multiple Tasks

In this section, a new version of ESP is described with extended evolution of morphology.

Replacing Morphological Constraints with Retesting

The initial implementation of the ESP system enforced strict limits on morphological changes after the completion of the first skill: Although changes to muscles and photoreceptors were allowed, segments and joints were fixed. Due to this constraint, previously learned skills could be expected to work reliably throughout the syllabus-based construction. On the other hand, this limitation makes it difficult to develop certain abilities later. For example, a creature may succeed in developing forward locomotion and the ability to turn left, but—due to the construction of a certain joint evolved for locomotion—be unable to learn to turn right, even after many generations of evolution.

Luckily, this limitation was undertaken only to make an initial success in the original system easier to achieve. It can be removed simply by expanding and modifying the fitness evaluations applied during learning: Instead of locking segments and joints after the first skill is developed, successive skills could be allowed to change these attributes, as long as new testing shows that such changes will not invalidate earlier abilities.

However, such an increase in testing threatens to make an already computationally demanding problem significantly more difficult, especially because the system is intended to be open ended. Assuming n skills and one independent test for each skill, full retesting of all previous skills at each step of the syllabus would produce an $\mathcal{O}(n^2)$ growth in the required testing, instead of the current linear growth.

Fortunately, the retesting can be considerably reduced by focusing it where it matters. Consider again the syllabus graph shown in Figure 6. The skills that have a direct influence on the creature's body are shaded, and will be referred to as *leaf* skills. These are: FORWARD LOCOMOTION, LEFT TURN, RIGHT TURN, and STRIKE. Once these skills are successfully established, the remaining non-leaf skills can be evolved independently (in an order that meets dependency requirements), without the need for any retesting. This approach stops the $\mathcal{O}(n^2)$ growth in testing requirements significantly earlier than would otherwise be possible—in the syllabus of Figure 6, for example, after four skills instead of 10 (assuming all leaf skills are learned first).

New ESP Algorithm

This subsection describes the implementation of the new, more general form of the ESP algorithm, taking advantage of the leaf skills. The method is comprised of two stages. The first stage consists of a fixed number of generations during which the new skill's control and body evolves, as de-

scribed in Algorithm 1. During this stage, existing encapsulated skills in the brain do not change, but if any morphological changes reduce these skills' fitness beyond a preset limit, the creature will be marked as unfit. In this way, the new skill is given free rein to adapt the body to its needs, provided that sufficient ability in all existing skills is retained.

The second stage runs for a fixed number of generations for each of the old skills, during which the morphology is temporarily locked–ensuring that the abilities achieved by the new primary skill are preserved–and each of the already existing skills gets a chance to reconcile itself to the new body (Algorithm 2). Since the morphology is fixed, these skills can develop completely independently–each skill can adapt to the new body, without degrading any of the other skills in the brain.

Proceeding in this manner, this extension of the ESP algorithm allows new leaf skills to seek their own adaptations to morphology as well as control, with a reasonable expectation that—as in the old system—existing skills will be maintained, allowing abilities to accumulate incrementally as in the original ESP.

Results

The experiments demonstrate the advantages of the continuing morphological evolution enabled by the extended ESP algorithm. In the first subsection (*Strike Results*), an experiment from the original ESP system is reproduced in the extended ESP system, with dramatically different results. In the second subsection (*High-Reach Results*), a learning challenge designed to highlight the extended system's advantages is presented, and detailed benefits are described. Note that, while extended ESP maintains original ESP's ability to construct complex hierarchical behaviors, that ability is inherited largely without modification in the new system. Therefore, the experiments in this paper are used instead to demonstrate the extended system's success in more challenging applications that were impossible in the original system. Video illustrating both of these result sections can be viewed online.³

Strike Results

An important part of the original ESP system's primary experimental result was to add a strike behavior to a locomoting creature (toward the larger goal of developing a complex fight-or-flight behavior). In this section, that portion of the old experiment is reproduced in the extended system, and a broad range of novel strategies and morphological changes is observed.

Strike in Original ESP Figure 1a depicts a creature evolved for locomotion in the underlying EVC system (which is common to both the original and extended versions of ESP). In original ESP, that creature consistently solved the challenge of producing a striking behavior by using its existing skeletal structure to either jump up and down or smash the ground with its limbs, without any opportunity to explore the potential for new strategies or better adaptation that might result from continuing full morphological development.

Strike in Extended ESP When the morphology is allowed to continue to evolve, however, new strategies become possible, and even old strategies may be better executed with morphological changes adapted to their specific needs. The extended ESP system develops a variety of such solutions, as can be seen in Figures 1b through 1f.

High-Reach Results

The second experiment was designed to highlight the benefits of the extended ESP system over the old implementation. Specifically, a selection of three different locomoting creatures was evolved to learn the additional skill of reaching for a high target, and the subsequent differences of results for the original and extended ESP implementations were examined in detail. The extended ESP system led to two types of improvements: 1) increased diversity of results, and 2) increased numerical fitness.

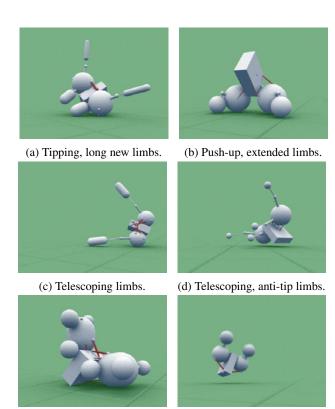

Figure 7: Greater variety through continued morphology evolution. The locomoting creature of Figure 1a was further evolved using the extended ESP system to adapt to a high-reach task. The results demonstrate the potential of continued morphology evolution to produce a great degree

(f) Jump, swing extensions up.

(e) Tip with enlarged limbs.

of useful variety.

Greater Variety The locomoting creature of Figure 1a was evolved toward the new high-reach goal, using both the original and the extended ESP implementation.

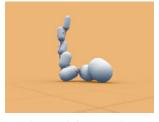

In the original ESP system, only two strategies were observed, within which the results were extremely uniform. Using morphology unchanged from the original locomotion result, all such creatures developed to either jump as high as possible, or reach a limb up by tipping over onto the other limb. In both cases, the results were limited by the inability of skeletal morphology to adapt to this new task.

In the extended ESP system, in contrast, a wide variety of results was observed, in which a number of novel strategies were used, often to great effect. These solutions are illustrated in Figure 7 (a) through (f).

Better Fitness Another successful solution to the locomotion task produced by the original ESP is shown in Figure 8a. This snake-like creature achieved a high reach by extending one end of its long morphology, while the rest of the body maintained balance.

Extended ESP improved upon this creature by changing

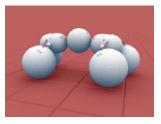

(a) Original ESP result.

(b) Result in new ESP.

Figure 8: Improved fitness via continued morphology evolution. These results demonstrate how the extended ESP system (b) can produce better fitness values (i.e., a higher reach) than the original ESP system (a) by allowing the addition of new body segments.

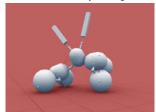

its morphology for the secondary task, while its strategy remained unchanged (Figure 8b). It grew an additional body segment that enabled the higher reach, while allowing it still to perform locomotion to acceptable standards.

(a) Initial locomoting creature.

(b) Subtle body changes.

(c) More obvious body changes.

(d) Dramatic changes in morphology.

Figure 9: Greater variety and improved fitness. The initial locomoting quadruped (a) is evolved for high reach in the extended ESP system (b)-(d). Through a variety of strategies, each of the extended ESP creatures scores better on this new task than any creature from the original ESP system.

Greater Variety and Better Fitness The relatively complex quadruped seen in Figure 9a was a third type of solution developed by the underlying EVC system for the locomotion task. In continued evolution of the high-reach task in the original ESP system, this creature's results were again extremely uniform in approach and fitness. They all reached up with a single limb, and all with approximately equal success. In the extended system, the ability to continue to adapt morphology to this new task led to a diverse set of useful

results, all of which were also more fit than those produced with the original technique.

For example, Figure 9b depicts a creature that pursues the same strategy as the creature in Figure 9a, yet does so more effectively due to subtle morphological adaptations. In Figure 9c, more obvious morphological adaptations have been added to further exceed the uniform performance limit experienced by this creature in the original system, while still employing the same basic technique. In Figure 9d, even more dramatic changes to morphology provide a new way of solving the high reach: This creature employs a new pair of tall, dedicated limbs to even further exceed the performance of the original ESP system.

Discussion and Future Work

Although the extended ESP algorithm has removed the original system's explicit limitations on body changes after the first skill, development of morphology throughout the acquisition of complex skills is still not fully general and completely unlimited. First, the retesting requirements would make morphological development impractical if continued through too many steps of leaf skill addition. To mitigate this issue in the future, it may be possible to do the retesting periodically rather than universally, and run the tests in parallel. Also, the more leaf skills there are, the more likely it is that the morphological change required by one skill is harmful to the others. This limitation is more difficult to overcome, and indeed it reflects the conflicting demands that any creature faces when dealing with complex environments.

In principle, it would be desirable to continue morphology evolution throughout all skill adaptations—not just for those skills that are leaves in the syllabus graph. In this manner, it might be possible to develop morphologies that make transitions between skills easier—for example by making the creature more stable or more agile. To make such evolution possible without increasing testing too much, a rolling horizon of "leaf" skills that travels through the syllabus hierarchy might be implemented. The idea is that once a lower skill will no longer be explicitly required for any subsequent skills, it need not be retested or maintained at all. With a well-chosen sequence of skill learning, an approximately constant-sized wave of "leaves" might result, sweeping gradually through the hierarchy.

Another potential area for future study that might be possible with extended ESP is to increase the morphological complexity of EVCs. While it was not investigated in this paper, the ability of the body to embody multiple types of physical intelligence simultaneously could ultimately lead to a greater degree of physical complexity, and thereby more interesting and capable EVCs.

Conclusion

This paper described an extension of the original ESP system to continue adaptation of morphology beyond the initial

skill, while still incrementally producing high-complexity behaviors. The benefits of this continued adaptation were demonstrated through experiments in which the extended ESP system generated a greater variety of solutions and solutions with higher fitness. Therefore, in the future, this method should make it possible to build EVCs with complex and believable behavior.

Evolving Morphologies with CPPN-NEAT and a Dynamic Substrate

Daniel Richards and Martyn Amos

School of Computing, Mathematics & Digital Technology, Manchester Metropolitan University D.Richards@mmu.ac.uk

Abstract

Recent advances in fabrication technologies open up exciting opportunities to manufacture entirely new types of physical materials and structures. These have varied and specific mechanical properties, which can be exploited in a number of engineering applications, and a growing area of research concerns the generation of two- and three-dimensional designs using these materials. However, the computational tools required to explore large spaces of possible 2-D and 3-D morphologies remain underdeveloped. State-of-the-art evolutionary approaches such as CPPN-NEAT HyperNEAT-LEO are often used to explore possible 2-D and 3-D designs, but their ability to construct efficient solutions for practical use in engineering domains remains in question. In this paper, we present an extension of CPPN-NEAT, in which nodes grow connections across a dynamic substrate, and illustrate this by creating efficient 2-D truss structures. Using four benchmark problems, we then demonstrate that our CPPN-NEAT model outperforms HyperNEAT methods for approximating specific connectivity patterns, and suggests important clues regarding how to best harness generative and developmental representations to build scalable and high-performance physical morphologies.

Introduction

Processes of evolution and development have shaped a vast array of physical structures. The desire to construct artificial structures with similar levels of complexity and efficiency is a driving force behind much of contemporary engineering. Recent advances in manufacturing technologies, specifically additive manufacturing (i.e. 3-D printing), open up the very real possibility of fabricating high-performance, physical designs that exhibit complex bio-inspired morphologies and behaviors [1-3]. Critically, this enhanced ability to control how and where material is distributed within structures enables the construction of entirely new classes of materials and objects, for use in various engineering domains. For example, at small scales, bone tissue scaffolds can be fabricated with bioactive glass to exhibit specific mechanical properties, such as high resistance to fracture [4]. At larger scales, these advances suggest vast potential for applications such as flexible cellular microstructures for prosthetic limbs [5], morphing wing designs for aerospace applications [6], and next-generation architectural designs [7,8].

While new fabrication hardware is facilitating exciting opportunities for engineering domains, the computational tools needed to fully exploit these technologies and aid

discovery of functional morphologies with novel mechanical properties, remain relatively underdeveloped.

As noted by Hiller and Lipson [9], well-known structural optimization algorithms, such as homogenization techniques [10], can already successfully address simple design problems such as 2-D and 3-D truss structures. However, because they rely on prior knowledge of how to exploit local gradient information, they are limited in their ability to discover complex designs that meet higher-level *functional* goals.

To address this limitation, evolutionary algorithms are often used to explore large design spaces and generate efficient solutions. Evolutionary methods are potentially useful because they can explore search spaces when no problem specific knowledge exists. However, evolutionary algorithms have their own set of limitations when applied to engineering domains. These include: lack of scalability [11], limited ability to ensure buildable solutions [12], inability to guarantee global optima [13] and difficulty in applying them to design exploration (i.e. beyond late-stage parameter optimization) [14].

Various work based on the NEAT (Neuroevolution of Augmenting Topologies) model (specifically, CPPN-NEAT [15, 24-26] and HyperNEAT [27, 28]) suggests the existence of exciting opportunities for addressing many of these issues, critically offering key advantages in terms of scalability. However, there still exist significant challenges relating to the use of these approaches for building 2-D and 3-D morphologies for engineering domains. For example, Devert et al [20] have recently highlighted critical "approximation accuracy" limitations of HyperNEAT when applied to 2-D truss structure optimization. Additionally, Fenton et al [32] note that ANN-based methods are less desirable than grammatical systems, due to the difficulties of imposing physical constraints.

In this paper, we precisely address these two major issues and present an approach that combines NEAT with Compositional Pattern-Producing Networks (CPPN). Specifically, this approach exploits growth and relative targeting of connections on a dynamic substrate to: (A) create 2-D truss structures that out-perform those produced by similar HyperNEAT approaches on four well-known topology optimization benchmark problems, and (B) enable simple ways of embedding problem-specific constraints for engineering applications. We first review related work, and then present our model, demonstrating how it extends a typical CPPN-NEAT method. We describe our experimental setup and present our results, before concluding with a discussion and suggestions for further work.

Background

Generative and developmental representations offer a powerful framework for creating 2-D and 3-D designs [16,17]. Kicinger et al [18], present a generative representation, based on cellular automata, to evolve tall steel structures for building design. Kowaliw et al [19] use a novel embryogeny to evolve 2-D truss structures. Recently, Devert et al [20] demonstrate a novel ontogenic approach for 2-D truss optimization. For a comprehensive review of evolutionary structural design methods, see [21] and [22].

Recent work, particularly within the area of evolutionary robotics, demonstrates the construction of diverse 2-D and 3-D morphologies by evolving CPPNs [15] with Stanley and Miikkulainen's NEAT algorithm [23]. For example, Clune and Lipson [24] use CPPN-NEAT to evolve 3D printed objects; Cheney et al [25], evolve virtual creatures with novel morphologies comprising multiple materials; Hiller and Lipson [9], evolve multi-material physical objects to meet high-level functional goals, such as specific deformations of 3-D beams; Auerbach and Bongard [26] evolve virtual creatures with diverse locomotive behaviors; and Szerlip and Stanley [27] use HyperNEAT-LEO [28,29] to evolve diverse, functional 2-D designs for the simulation engine *Sodarace*.

We suggest that NEAT-based approaches offer significant potential for use in engineering domains, by enabling the discovery of novel material compositions with *specific mechanical properties* and *high-level functionality*. However, as highlighted by Devert et al [20], HyperNEAT currently has problems with accurately generating specific connectivity patterns, and this limitation makes it difficult to optimize even relatively simple 2-D truss structures. At the core of this issue is that HyperNEAT struggles to produce *modular* networks. Verbancsics and Stanley [29] show that by adding a bias towards creating local connections, HyperNEAT-LEO can create modular solutions and improve performance on various control problems. However, we believe that this approach, in its current form, is not enough to create efficient 2-D and 3-D morphologies – we support this claim in the Results section.

The second key challenge for CPPN-NEAT, when applied to engineering problems, is the inclusion of *physical constraints*. For example, to apply standard structural analysis techniques, solutions must have all parts suitably connected (i.e. no disconnected elements), yet dealing with fully connected solutions can be computationally expensive. For this reason, grammatical systems are often the favored generative approach to evolving buildable 2-D and 3-D solutions. Notably, Hornby and Pollack [30] evolve L-System grammars to create buildable table designs; Rieffel and Smith [31] use a grammatical approach to grow soft-bodied robot morphologies; and Fenton et al [32] use grammatical evolution to optimize simple truss structures and restrict the design space to a set of standard member sizes.

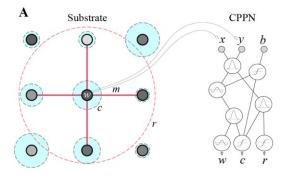

The key insight in this paper is that CPPN-NEAT can control simple (grammar-like) growth rules that play out on a 2-D (or 3-D) grid and generate local connectivity patterns, which are interpreted as physical designs. The benefit of this extra layer of abstraction is that we can: (A) more accurately approximate specific connectivity patterns; (B) easily enforce physical constraints and (C) exploit CPPN-NEAT's scalability and capacity to create geometric regularities.

Methods

Representation

CPPN-NEAT and HyperNEAT have already been described in detail [15, 24-29, 33], so we provide only a brief summary, and mainly focus on how our proposed method differs from previous work. CPPNs are similar to neural networks, yet nodes may contain a variety of different mathematical functions and can be evolved using NEAT [23]. CPPN-NEAT can be used to evolve complex geometric patterns. For example, 2-D patterns can be drawn by querying a CPPN and setting the color of each pixel on a canvas as a function of its x and y coordinates. Similarly, HyperNEAT uses CPPNs to specify the weight, w, of all connections in a larger fully connected feed-forward neural network (termed the "substrate", to distinguish it from the CPPN, which is also a network), by querying the coordinates of each input node i and output node j. That is, for each connection, the CPPN inputs x_i , y_i , x_j , y_i and outputs w.

The key idea in this paper is to use CPPNs to create 2-D morphologies in a similar manner to HyperNEAT (as [27]), but with *one key difference*. That is, instead of querying a fully connected *fixed* substrate of possible connections and specifying the dimensions of individual truss members, we use CPPNs to generate growth instructions for each node as a function of its x and y coordinates (Fig 1).

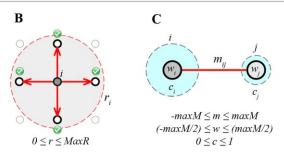

Figure 1. Growth of structural elements. (A) Nodes are initialized with growth instructions by querying a CPPN. Nodes grow connections using three properties: r, w, c. (B) Each node has a range of influence, r, and is permitted make connections between all other nodes which are within this radius. (C) Nodes also have a weight, w, and a concentration, c. Connections between nodes i and j have a cross-sectional area, m_{ij} , which is created by summing w_i and w_j , with a potential bias that is determined by concentrations c_i and c_i .

The shift from directly querying connections (specific targeting) to querying nodes and then growing connections (relative targeting of connections) provides at least three interesting possibilities when generating network structures. Firstly, it imposes a hard-coded bias towards creating local connections. That is, unlike [29], in this approach the ability to create longer connections actively increases the number of possible connections in the entire structure, thus enlarging the dimensionality of the problem. This means that networks with shorter, local connections are often easier to optimize, and thus more likely to emerge. Secondly, fixed fully connected substrates can be replaced by dynamic substrates, where the maximum connectivity of any individual node varies across the substrate as a function of growth. Notably, the bottleneck in many engineering problems is the computation time required for evaluation, so eliminating the need to simulate fully connected substrates can result in significant savings of CPU time. Thirdly, as we have previously shown [34], growth provides a useful mechanism for imposing necessary physical constraints. For example, during growth, individual nodes can be limited to a maximum or minimum number of connections.

As shown in Figure 1, nodes are initialized by querying a CPPN (using Cartesian coordinates as inputs), and then grow connections on a larger substrate, where: $-1 \le x \le 1$ and $-1 \le y \le 1$. The CPPN uses three inputs (x and y coordinates and one bias) and returns three output values (w, c, r). Each connection has a cross-sectional area, m, which is defined by summing the weight, w, from each endpoint node and potentially applying a small bias based on the concentration value, c, of both end nodes. Thus, to define the cross-sectional area m_{AB} we use:

bias =
$$(max(c_A, c_B) - min(c_A, c_B)) \times Q$$

if $(c_A \ge 0.5 \text{ and } c_B < 0.5)$
 $m_{AB} = (w_A \times (1 + bias)) + (w_B \times (1 - bias))$
else if $(c_A < 0.5 \text{ and } c_B \ge 0.5)$ (1)
 $m_{AB} = (w_A \times (1 - bias)) + (w_B \times (1 + bias))$
else $m_{AB} = w_A + w_B$

Where m_{AB} is the cross-sectional area of the connection between nodes A and B, c is the concentration value, w is the weight of each node, and Q in a fixed coefficient value used to determine the maximum bias. In this paper, we set Q=0.2 for all problems.

Each node has a minimum and maximum range, r. To avoid matrix errors during structural analysis, we enforce a minimum degree of connectivity for all nodes (Fig 2B).

There are two significant implications of this; firstly, nodes can be completely "switched off" by reducing the r below the minR threshold. This means that no other nodes can connect, and this provides a useful mechanism for sculpting network topology. Secondly, because nodes contain useful information about their immediate neighborhood, null connections that do not contribute to the node's minimum connectivity are easily eliminated, excluding them from computationally expensive analysis. For example, fully connected solutions (Fig 2C), where all members have null cross-sectional areas ($m \le 1.e^{-7}$), can be converted into Figure 2B before evaluation, which is more computationally efficient to simulate. Note, if minimum connections are defined as "null", we use a very small cross-sectional area ($m = 1.e^{-7}$), as is standard in truss optimization.

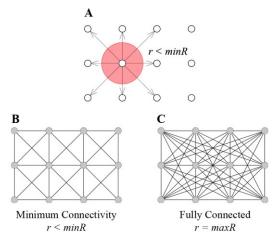

Figure 2. Enforcing minimum and maximum connectivity. (A) Each node must at least connect to all of its immediate neighbors. This distance is defined as the minimum connectivity limit: minR. If a node's r < minR, all connections made to this node become null and it is connected to its immediate neighbors. (B) Minimum connectivity of all nodes. (C) Fully connected structure.

Truss structures (as shown in Fig 2) must not contain overlapping (duplicate) connections; therefore to enable a dynamic substrate, further constraints must be applied to ensure that such connections are disallowed. To achieve this, we modify our "data-tag" approach used during node interactions, described in detail in [34]. As in [34], nodes swap and manage a small set of data-tags to keep track of their existing and new connections. Data-tags are checked before new connections are made, to avoid creating duplicates. Additionally, to avoid overlapping connections, we constrain nodes so that they are only permitted to connect to neighbors when there are no intermediate nodes.

Static Analysis

To evaluate the 2-D structures we use the linear *direct* stiffness method [35], which is a common finite element method (FEM). The process involves modeling the stiffness properties of each truss member and using the information to assemble a larger global stiffness matrix, K(a), which describes the mechanical behavior of the entire structure:

$$K(a) = \sum_{j=1}^{n} a_j K_j$$

Where a_j is the cross-sectional area of the *jth* truss element and K_j is the member stiffness of the *jth* truss element. When M forces $(f_1,...,f_M)$ are imposed on nodes in the truss they react and move. The displacement, u_j of loaded nodes is solved with the linear system:

$$K(a)u_k = f_k, \qquad k = 1, \dots, M$$

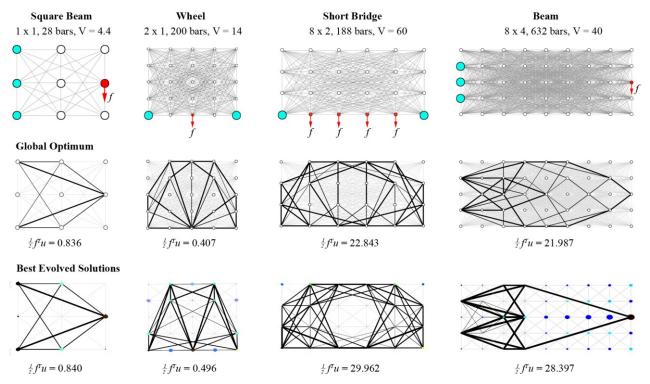

Figure 3. Benchmark Problems. (Top row) Four benchmark problem instances. Blue nodes have restricted degrees of freedom, and red nodes have an imposed one unit load in the direction of the arrow. The descriptions above give (a) x and y dimensions of truss (note: figures show the *substrate*, not the absolute x and y dimensions of each truss as used in FEM analysis), (b) number of bars and (c) the volume constraint, V (see [36] for further details). (Middle row) Global optima (from [36]). (Bottom row) Best evolved solutions using CPPN-NEAT with dynamic substrate. Here node color and size represent the node properties c and r, respectively.

Benchmark Problems

We test our method using the same truss benchmark problems as those used by Devert et al [20] (Fig 3), and compare our results with similar HyperNEAT methods.

The benchmark problems are relatively simple, have known global optima [36], and can be solved perfectly using evolutionary approaches with direct representations. However, as highlighted by Devert et al [20], HyperNEAT (HyperNEAT 3.0 C++ package with default parameters) struggles to generate good solutions to these problems. They argue that, due to this limitation, ontogenic representations are superior. However, we suggest that such ontogenic representations are only applicable when problems have valuable gradient information that is already known to be exploitable. For example, Devert et al's ontogenic encoding uses 32 FEM calls per solution and works by iteratively querying a CPPN, each time inputting the structural strain of each truss member and returning an incremental modification of the cross-sectional area. This technique does indeed provide superior solutions to similar generative representations. However, when such gradient information is readily available and the correlation between parameters is well understood (i.e. if member strain is low, reduce cross-sectional area), existing homogenization techniques are generally orders of magnitude faster [10, 37].

Since our motivation is to explore large search spaces where useful gradient information is largely unknown, and homogenization techniques do not exist, we argue that better generative representations will provide a valuable way of discovering complex material compositions in various problem domains [1-9]. Consequently, we compare our method against: (1) Devert et al's recorded HyperNEAT results [20], (2) HyperNEAT with a locality seeded LEO [29], and (3) our model without the dynamic substrate, where r is binary either "on" with full connectivity, or "off" (r < minR) with all null connections (see Fig 2).

We use the common topology optimization objective:

$$\min \frac{1}{2} f^T u$$

Subject to the constraints:

$$\sum_{j=1}^{n} a_j l_j \le V$$

$$a \in [0.1]$$

Where: a_j is the cross-sectional area (a continuous value between 0 and 1) of the *jth* bar, l_j is the length of the *jth* bar, and V is a problem specific volume constraint (see Fig 3).

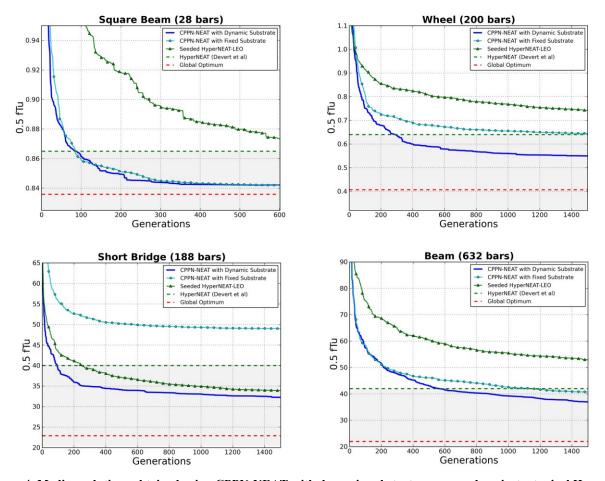

Figure 4. Median solutions obtained using CPPN-NEAT with dynamic substrate, compared against a typical HyperNEAT method (indiated as a fixed threshold value, showing the median best solutions obtained by [20] over an equivalent number of FEM evaluations, from 64 independent runs). HyperNEAT with a seeded LEO [29], our CPPN-NEAT with fixed substrate, and the known global optimum (taken from [36] – indicated as a dotted line). On all problems, CPPN-NEAT with a dynamic substrate performs best.

Experimental Details

For all benchmark problems, we perform 20 independent runs, each with a population of 150 CPPNs, evolved for a maximum of 1500 generations. As NEAT is a maximization algorithm, we adapt the previously outlined objective function to define our fitness function:

$$max \frac{1}{\frac{1}{2}f^T u}$$

We use our own java implementation of NEAT and HyperNEAT-LEO. CPPNs use the following activation functions: *Gaussian, Cosine and Sigmoid* with equal probability of being produced. We promote 25% of the population with elitism, and there is an 80% chance of mutating individuals after crossover.

Mutation rates are 0.03, 0.05 and 0.8 for adding a new node, adding a new link and perturbing connection weights, respectfully – and probability of interspecies mating is 0.001. We use a dynamic compatibility threshold, where the target number of species is 10 and the niche size required for elitism is 5. Finally, we set compatibility coefficients to: $c_1 = 2.0$, $c_2 = 2.0$, $c_3 = 1.0$.

The Young's modulus of all non-null beams is 1.0 and for null members is 0.0. All force loads (shown with a red arrow in Fig 3) have a magnitude of 1.0 and are in the direction of the arrow. Each problem has a maximum volume of material, V, if any solution has a *volume* > V, the cross-sectional area of all members are linearly scaled to meet V. The minimum cross-sectional area of any truss member is $1.0e^{-7}$ and anything below this value is null. Finally, for all of these experiments, the maximum cross-sectional area (maxM) is 1.0.

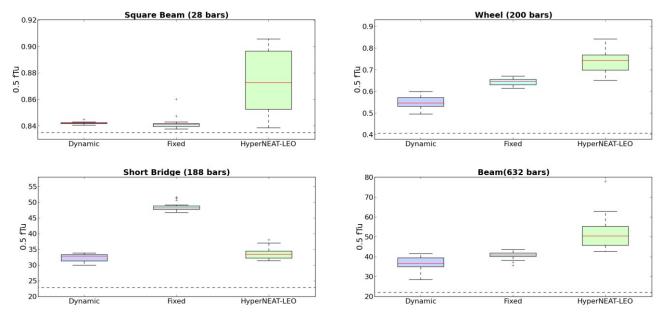

Figure 5. Best solutions obtained for different problems over 20 independent runs for CPPN-NEAT with dynamic substrate, CPPN-NEAT with fixed substrate and the seeded HyperNEAT-LEO. Dotted lines indicate global optima.

Results

Our results demonstrate that CPPN-NEAT with dynamic substrate outperforms both standard HyperNEAT and seeded HyperNEAT-LEO on all four benchmark problems. Specifically, the dynamic property of the substrate, coupled with the ability to silence nodes during growth (i.e. when r < minR, see Fig 2), enables our CPPN-NEAT method to create better truss solutions and more closely approximate specific connectivity patterns of the known global optimum (Fig 3).

Figure 4 shows the median solutions obtained using our dynamic method in comparison to: (A) standard HyperNEAT (as described in [20]), (B) HyperNEAT-LEO with a seeded bias towards expressing local connections [29], and (C) our CPPN-NEAT method using a fixed and fully connected substrate. As shown, the CPPN-NEAT with dynamic substrate converges faster than all other methods and quickly improves on the best solutions found by [20]. Figure 5 shows the best solutions obtained with each approach; we see that CPPN-NEAT with dynamic substrate improves on the best median solutions generated with the seeded HyperNEAT-LEO by 3.5% on the smallest *square beam* problem, a more substantial 26.5% on the *wheel*, 2.8% on the *short-bridge* and 27% on the largest *beam* problem.

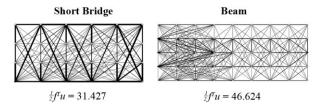

Figure 6. Best truss designs obtained with the seeded HyperNEAT-LEO over 20 independent runs.

Interestingly, the seeded HyperNEAT-LEO performs well on the *short-bridge* problem and significantly outperforms standard HyperNEAT and CPPN-NEAT with fixed substrate. We attribute this increased performance to the substrate configuration of the problem. That is, the short-bridge problem uses a 5 x 3 grid of nodes, yet the x and y dimensions of the substrate of the are always equal $(-1 \le x \le 1 \text{ and } -1 \le y$ $\leq I$). This means that, unlike the square-beam and wheel problem, nodes are not equally spaced in the substrate, so here the HyperNEAT-LEO with seeded bias for creating local connections is able to improve solutions. However, as shown in Figures 4 and 5, the seeded HyperNEAT-LEO actually performs much worse on the larger beam problem, which has similar (8 x 4) substrate configuration. To understand this difference, we can look at the type of truss designs produced by seeded HyperNEAT-LEO (Fig 6). Here we see that a key problem is that it struggles to eliminate non-essential connections, and instead tends favor highly connected designs. This tendency becomes increasingly detrimental to truss optimization as the problems scale up and we increase the number of possible connections.

Critically, CPPN-NEAT with dynamic substrate *does not* suffer from this problem, and, in contrast, evolves solutions with much more clearly differentiated network morphologies (Fig 3). Interestingly, we observe that during the early stages of evolution, CPPN-NEAT with dynamic substrate tends to create truss structures with minimal connectivity patterns that become more complex over time (similar to NEAT) as structurally significant nodes in the substrate become densely connected and establish longer connections.

These results suggest that while seeding HyperNEAT-LEO with a bias towards creating local connections is clearly a valuable method for improving performance and modularity in ANN problem domains [39], when creating 2-D (and most likely 3-D) designs, CPPN-NEAT with dynamic substrate provides superior solutions.

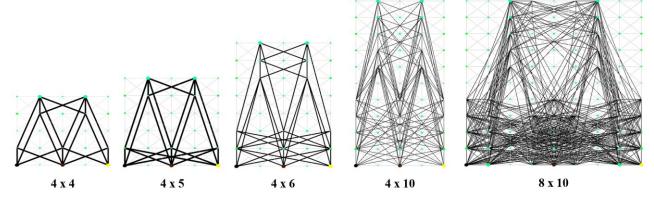

Figure 7. Scaling trusses without further evolution. The physical dimensions and substrate resolution (number of nodes in x and y axis) can be manually manipulated following evolution, and trusses retain many evolved characteristics.

Discussion

We present a novel extension of CPPN-NEAT for evolving functional 2-D network structures. We show that CPPN-NEAT with a dynamic substrate outperforms similar state-of-the-art HyperNEAT methods on four well-known benchmark problems for topology optimization, and more accurately approximates specific connectivity patterns of known global optima.

We acknowledge that none of the CPPN-based methods presented here are able to find the global optimum for these problems, unlike state-of-the-art evolutionary strategies, which do converge to global optima (as shown by Devert et al [20]). However, methods that rely on *direct* representations are prone to issues of (lack of) scalability, and are thus limited to addressing relatively simple design problems. Generative encodings will benefit various engineering domains [1-9] and ultimately allow us to exploit advanced manufacturing technologies and capabilities (such as high-value functionally graded solutions, multi-material composites, and so on.) In this context, "optimality" is less important than the ability to obtain new types of morphology that exhibit some specific functional behavior(s). CPPN-NEAT with dynamic substrate may hold important clues towards achieving this goal, and here we have presented an early proof-of-principle (albeit on a simple benchmark problem). In this concluding section, we describe additional properties of CPPN-NEAT with dynamic substrate that will offer useful trajectories for further research.

The key feature of our model is a more "biologically plausible" method of creating connectivity patterns. Instead of using HyperNEAT to define properties of specifically identified connections, we use a CPPN to control an additional network growth process. During this process, nodes use relative positional information to target surrounding nodes and grow locality biased connectivity patterns. In this paper, our growth step occurs just once to build 2-D truss designs. However, if we were to set our model within a physics-based simulation environment, nodes could continue to build and destroy connections over the lifetime of the structure, as nodes move. Such an approach could provide interesting *locomotive* behaviors that may be extremely robust to perturbation.

A second interesting implication of creating connections through growth is that we define new opportunities to exploit *node-based information*. For example, in the benchmark problems used in this paper, nodes are explicitly encoded with information that is used to (A) restrict degrees of freedom and (B) impose physical loads. In many engineering problems, this type of information is known well before optimization takes place, and could therefore easily be fed into CPPNs as additional information. Notably, Clune et al [24], have previously demonstrated that feeding additional information, relating to distance to center of a 3-D grid of voxels, can be exploited to create more rounded geometric features in solutions. Consequently, the ability to utilize information about boundary conditions may be useful in future work.

Thirdly, an exciting property of CPPNs is that the solutions they encode effectively obtain *infinite resolution*. For example, 2-D pictures evolved with CPPNs never get pixelated when they are scaled up. Similarly, truss designs evolved with CPPN-NEAT can be manipulated following evolution, and retain many of their characteristics (Fig 7). This property could have at least two useful applications. Firstly, the ability to increase resolution during evolution may help to optimize large-scale truss and/or network-based structures. Secondly, this added flexibility may provide new possibilities for *interactive* evolution, allowing network-based solutions to be explored and scaled in real-time. Indeed, in our current Java-based method, users can extract parameters of the underlying CPPN (connection weights) and manually adjust evolved solutions in real-time.

In addition to these avenues of enquiry, we will investigate the dynamical behavior of our model, in order to better understand (and improve) the method. In particular, we anticipate significant future savings in computational effort as we scale up the size of the substrate, due to our method avoiding non-essential connections between nodes. Future work will rigorously investigate the absolute performance improvement that may be obtained with our model on non-trivial problem instances.

Finally, further work is now underway to explore more complex 3-D problems with non-trivial mechanical properties (such as compliant mechanisms). Notably, the method presented in this paper can easily be extended to 3-D design by simply adjusting the FEM solver (see Fig 8).

Collective Robotics

Understanding the Role of Recruitment in Collective Robot Foraging

Abstract

When is it profitable for robots to forage collectively? Here we compare the ability of swarms of simulated bio-inspired robots to forage either collectively or individually. The conditions under which recruitment (where one robot alerts another to the location of a resource) is profitable are characterised, and explained in terms of the impact of three types of interference between robots (physical, environmental, and informational). Key factors determining swarm performance include resource abundance, the reliability of shared information, time limits on foraging, and the ability of robots to cope with congestion around discovered resources and around the base location. Additional experiments introducing odometry noise indicate that collective foragers are more susceptible to odometry error.

Introduction

Foraging is a well-studied behaviour in both animals and robots. Just as biological species implement foraging strategies that are adapted to their specific niches, it would be desirable to tailor robot foraging strategies to the particular challenges that they face. For example, large animals like wolves, hyenas or lions forage alone when their food is dispersed, while social insects such as ants, bees and termites recruit their nest mates to collectively obtain food from a patch that can be exploited over a number of visits. When should robots forage collectively?

Since collective strategies that rely on communication, co-ordination, interaction, etc., will tend to require more expensive robots and more programming time than independent, individualist robots, it is important for designers to resort to collective strategies only when they significantly improve collective performance.

In this work, the resource gathering performance of a simulated swarm of collective robots that recruit each other to profitable resource locations is compared with that of a swarm of individualists that forage independently. Swarms are evaluated across a range of scenarios that differ in terms of the challenge involved in locating resource deposits, as well as their spatial distribution and variation in terms of volume and quality. By analysing variation in performance

we aim to uncover which environmental properties favour collective foraging approaches in robot swarms.

Background

Most animals, especially carnivores, perform solitary foraging (Gittleman, 1989). For example, forest birds search for insects alone if food is sparse and many insects are needed (Robinson and Holmes, 1982). Frigate birds searching for fish also do so solitarily, despite the fact that they live in colonies. They tend to disperse while searching in order to optimise their probability of success and rarely return to an area where they have previously fed (Weimerskirch et al., 2004). Similarly, hyenas (Holekamp et al., 2012), lionesses (Stander and Albon, 1993) and chimpanzees (Busse, 1978) hunt alone during periods of sparse prey abundance.

By contrast, some creatures forage collectively, recruiting their collaborators to profitable food locations by sharing information. Recruited foraging is most common in social insects and appears either in the form of stigmergy or direct signalling. Stigmergy is utilised by ants (e.g., Beekman, 2001) and termites (Arab et al., 2012) when they lay pheromone trails that lead to food, changing their environment such that it stores useful information that guides the behaviour of recruited conspecifics.

Bees, however, rely on directly influencing their nest mates. Successful foragers return to the nest to perform a waggle dance that communicates both food quality and location (relative to the dance floor) to watching bees (Seeley, 1994; Granovskiy et al., 2012). Flexibility and sophistication is achieved by both scouting for new food sources and re-evaluation of old foraging sites, allowing bee colonies to rapidly adapt to changing flower quality (Seeley, 1992; Biesmeijer and de Vries, 2001)

A number of approaches have been taken to implementing foraging in robot swarms, including random walking robots that forage independently (e.g., Hoff et al., 2010), bucket brigading swarms where each robot is only responsible for its own portion of a foraging area and items travel towards a base location by being passed between robots (e.g., Shell and Mataric, 2006; Lein and Vaughan, 2009), robots that di-

rectly signal to each other about where items can be found (e.g., Rybski et al., 2004; Jevtic and Gazi, 2010; Sarker and Dahl, 2011), and swarms that use stigmergy, where certain robots act as beacons, maintaining an information gradient towards a deposit (e.g., Hoff et al., 2010).

It is notable that robot swarms are often investigated in a single environmental scenario with a specific distribution of target items (typically a uniform random distribution) or in scenarios that are particularly suited to the swarm strategy. An exception to this was the work of Hoff et al. (2010) who compared a group of randomly walking individualists to a swarm that used stigmergy. However, the individualists in these experiments were highly disadvantaged as they had to find the drop off location by random walk every time they acquired a target and thus performed very poorly.

Here we implement an idealised and simplified version of bee-like recruitment in which robots that are near to each other may exchange subjective information about recently visited resource locations. By exploring a range of environments, we aim to discover both the conditions that favour collective foraging and those that do not.

Methods

Simulation environment

Robots of size 10×10 units were placed in a 4000×4000 continuous-space arena with periodic boundaries (i.e., a torus) featuring a centrally located circular base with a diameter of 100 units. One simulated second consisted of 50 update loops (hereafter "updates") and an experimental run lasted 600 simulated seconds. One robot travelling at top speed in a straight line could traverse the full length of the world in 80 seconds (i.e., travelling at 50 units per second).

A set of foraging scenarios were defined, each characterised by the number, N_D , of 5×5 resource deposits in the environment and their properties. Each deposit, i, comprised V_i units of material, where each unit had a deposit-specific resource quality, $Q_i \in [0,1]$, such that the total resource in a deposit was equal to V_iQ_i . Each robot could extract up to one unit of volume from a resource deposit per visit, reducing the deposit's volume and extracting Q_i resource to be returned to the robot base. Once the entire volume of a resource deposit had been collected it ceased to exist in the environment and was not replaced.

By default, all deposits were distributed uniformly at random in space with each deposit having equivalent quality (Q=0.5). However, some environments featured non-uniform spatial distributions comprising a number of spatially clustered groups of deposits, and, additionally, some environments featured non-uniform quality distributions in the form of a number of higher-quality patches. Note that these patches did not influence the spatial distribution of deposits, only their quality.

Where the number of spatially clustered groups, N_G , was greater than zero, each of these groups featured 10 deposits

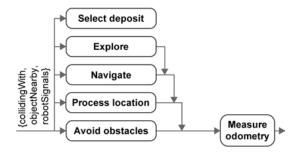

Figure 1: Subsumption architecture of the robot controller.

clustered within a 500-unit radius circular region and no deposits existed outside these groups. Where the number of quality patches, N_P , was greater than zero, each patch was centered on a deposit which was allocated Q=1, and the quality of the deposits around it decayed with distance, d, from the patch centre:

$$Q = \min\left(e^{-d^2/\beta\sigma_P^2}, \ 0.5\right),\tag{1}$$

where patch quality variance, σ_P^2 , was a scenario-specific parameter that controlled the size of the quality patch, and β was a constant factor set to 8×10^6 for all results reported here. In such scenarios, the quality, Q, of deposits outside of patches was scaled down by a constant factor in order to keep the total amount of net resource equal across scenarios. Quality patch centres were randomly chosen deposits with no more than one patch centre per group (when $N_G > 0$).

Robots

The simulated robots utilised a subsumption architecture (Brooks, 1986), where low-level behavioural modules such as avoiding obstacles could be overriden by motor commands of higher-level behaviours such as navigation towards a target (Figure 1). The individual modules communicated with each other by setting the robot's state and other internal variables stored in the robot's memory. A finite-state machine representation of the robot is depicted in Figure 2.

Robots were initially randomly oriented and located within the central home base which featured a beacon that allowed any robot to navigate directly home from any point in the arena (Pini et al., 2013).

Individualist robots (I-Swarm) performed a random walk to search for food, avoiding each other by backing up and turning by a random angle. When a deposit was discovered, one unit of volume was loaded (or the entire deposit if one or less than one unit remained) and returned to the base (navigating using the home beacon). On the basis of subjective odometry calculations, a robot returned to where it estimated the deposit was located if the energy efficiency, E_e , of the deposit was better than that of the worst deposit that it had found so far.

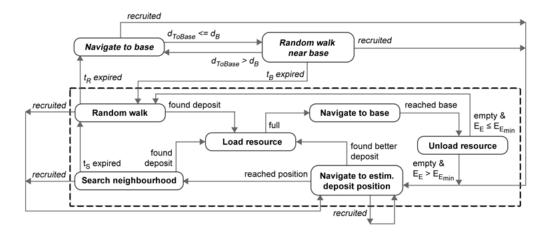

Figure 2: Finite-state machine representation of the robot controller. B-swarm logic is shown in italics outside the dashed box.

Estimation of energy efficiency was inspired by a model of bees (Seeley, 1994) and took into account the volume, V, and quality, Q, of the deposit, as well as the cost of revisiting it, calculated in terms of time and energy required to (i) reach it (1 unit of energy per simulation update), (ii) load it (5 seconds at 5 units of energy per update), (iii) return to base (5 units of energy per update) and (iv) unload it (2 seconds at 5 units per update):

$$E_e \sim \mathcal{N}\left(\frac{VQ-C}{C}, \sigma_e^2\right)$$
 (2)

$$C = \sum_{i=1}^{4} T_i * E_i, \tag{3}$$

where $\sigma_e^2 = 0.05$ was the variance of normally distributed estimation noise, and T_i and E_i were the time and energy per unit time required for each of the four foraging subtasks. It was also assumed that a robot could estimate the energy efficiency of a deposit from a maximum distance of 30 units.

Upon reaching a remembered location, neighbourhood search was undertaken for a maximum of $t_S=10$ seconds, comprising a random walk constrained within a distance of $r_S=120$ units around the estimated deposit location (Pini et al., 2013). The robot resumed random search if nothing was found, or if it could not reach the remembered location within 120 seconds. If, en route to a remembered location, a robot encountered a new deposit with superior energy efficiency, the superior deposit would be visited instead.

Odometry was used to estimate the location of a remembered deposit based on a robot's subjective impression of its rotational change $\Delta \alpha'$ and speed S' during locomotion. Odometry was affected by Gaussian noise on the actual values of rotation (α) and speed (S), simulating wheel slippage,

etc. (Chong and Kleeman, 1997; Martinelli, 2002):

$$\Delta \alpha' \sim \mathcal{N} \left(\Delta \alpha, \ \kappa \times \Delta \alpha \right),$$

 $S' \sim \mathcal{N} \left(S, \ \kappa \times S \right),$
(4)

where parameter κ scaled the variance of odometry noise.

Collective foragers (B-Swarm) employed the same basic foraging strategy as the I-Swarm, but could also signal to nearby robots (< 60 units) their estimate of a remembered deposit's location and its associated energy efficiency (Jevtic and Gazi, 2010). A robot was recruited to a signalled location if it either did not have the location of a deposit in memory, or if its remembered deposit had inferior energy efficiency. Additionally, a B-Swarm robot returned to the base and roamed within $d_B=200$ units of its centre for up to $t_B=120$ seconds if it could not find a deposit during $t_R=120$ seconds of random walk. In this way, unsuccessful foragers could discover deposit locations from robots returning to base to unload, mimicking to some extent the behaviour of bees (Biesmeijer and de Vries, 2001; Granovskiy et al., 2012).

Results

Three sets of simulation results are reported here. First, we explore the impact of varying both the number of robots and the number of deposits on I-Swarm performance in order to identify values for N_R and N_D that present an appropriate degree of challenge. Second, we compare the performance of I-Swarms and B-swarms over a range of foraging scenarios that differ in key respects. Third we explore the impact of odometry error on swarm foraging performance.

Calibrating N_R and N_D

I-Swarm performance was assessed in two basic scenarios, *Uniform* quality and *Patchy* quality, varying the number of

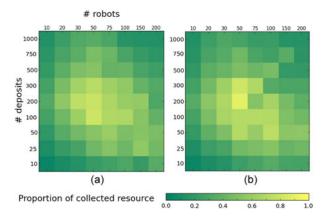

Figure 3: I-Swarm performance as a function of the number of robots and number of deposits in (a) *Uniform* quality and (b) *Patchy* quality scenarios. Each data point is the mean of 10 independent simulations.

robots, N_R , and the number of deposits, N_D (see Figure 3). In both scenarios, $V=200/N_D$, and deposits were distributed uniformly at random across the entire arena. *Uniform* quality deposits had Q=0.5. The quality of *Patchy* deposits was influenced by $N_P=30$ randomly located quality patches, each with $\sigma_P^2=0.01$.

In both scenarios, performance peaked for an intermediate number of robots and an intermediate number of deposits. With too few robots or too many deposits, not enough foraging trips could be carried out within the duration of a simulation. With too many robots performance deteriorated due to physical interference between foragers near the base. With too few deposits, performance was reduced by the increased challenge involved in discovering deposits far from the base.

In the *Patchy* quality scenario there was some evidence that performance depended on an interaction between N_D and N_R (influencing the degree of interference between robots) but the peak and overall shape of the performance distribution was not significantly altered. Consequently, in order to assess swarms in scenarios that varied in the challenge that they presented, and thereby avoid floor and ceiling effects, a range of values for $N_D \in [10,100]$ and $N_R \in [10\dots 100]$ were established and utilised for the remainder of the results presented below.

I-Swarm and B-Swarm Foraging Performance

A set of foraging scenarios were defined, varying in spatial distribution, volume, quality, etc.:

- Litter scattered in a field: a uniform random spatial distribution of equal quality deposits, with $N_D = 100, N_G = 0, N_P = 0, V = 2, Q = 0.5$.
- Large **Puddles** of rain water: like *Litter*, except deposits are ten times larger, $N_D = 10, V = 20$.

- Rare **Minerals**: a uniform random spatial distribution of patchy quality deposits located located at least 1500 units from the base, with $N_D=10, N_G=0, N_P=5, \sigma_P^2=0, V=20, Q=$ varied.
- Common Stones: like *Minerals*, but $N_D = 100, N_P = 10, \sigma_P^2 = 0.01, V = 2, Q = \text{varied}.$
- Nectar from flower clusters: 10 groups of 10 deposits each. Location of group centres was drawn from a uniform random distribution at least 500 units away from the base, with $N_D=100, N_G=10, N_P=3, \sigma_P^2=0.01, V=2, Q=$ varied.
- Lost **Cargo**: like *Nectar*, but with one group of equal quality deposits where $N_D=10,N_G=1,N_P=0,\sigma_P^2=0,V=20,Q=0.5$.

Variation in swarm performance across different scenarios (see Figure 4) can be explained in terms of three types of robot-robot intereference:

- 1. Physical interference caused by one robot obstructing another typically while foraging from the same deposit or returning to the base at the same time.
- Environmental intereference where one robot substantively alters the foraging environment of another by depleting its current target deposit.
- Informational interference, unique to the B-Swarm, where one robot's behaviour is influenced either positively or negatively by signals from another robot.

I-Swarms slightly but consistently outperformed B-Swarms when collecting Litter in swarms of less than 100 This advantage was statistically significant for swarms of size $N_R = 10$ and 20, and also significant across all $N_R < 100$ swarms when their results were considered together (Wilcoxon signed-rank test, p < 0.01). The fact that litter deposits were abundant and could be depleted in two visits meant B-Swarms suffered from informational interference that negatively impacted on performance. In theory, Stones presented a more significant challenge for both swarms since they were located further from the base and were, at least initially, harder to find. However, the slight advantage that I-Swarms experienced for Litter was extinguished in this scenario since B-Swarms could benefit from recruiting robots to the general location of the stones, and were thus able to match I-Swarm performance.

B-Swarms were able to collect more resources than I-Swarms in each of the other scenarios, where deposits were richer in volume but more difficult to discover, i.e., *Puddles*, *Minerals*, *Nectar* and, most strikingly, *Cargo* where all deposits were in one area far from the base. In this scenario, a B-Swarm of 100 robots was even able to collect more resource than an I-Swarm of the same size in an easier, *Nectar* collection task.

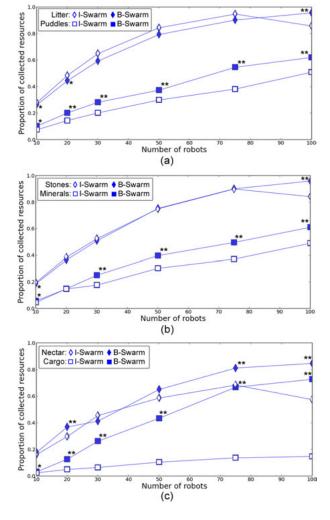

Figure 4: The influence of scenario type on the foraging performance (measured as the median proportion of resource collected over 20 independent simulation runs) of I-Swarms and B-Swarms of different sizes. Statistically significant differences between I-Swarm and B-Swarm performance in the same scenario are indicated with asterisks (Wilcoxon signed-rank test, ** p < 0.01, * p < 0.05). The average interquartile range was approximately 0.082.

An interesting effect of recruitment was also observed when 100-robot swarms foraged for *Litter*, *Stones* or *Nectar*. I-Swarms of this size suffered a drop in performance resulting from physical interference in the form of congestion around the base. By contrast, recruitment in B-Swarms caused smaller groups of robots to forage from neighbouring locations, meaning that foragers from one group solved the problem of avoiding each other near deposits in parallel with other groups. Such self-organisation led to a kind of spontaneous traffic management and consequent reduction

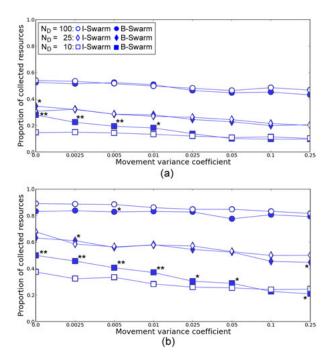

Figure 5: The influence of odometry error (κ) on the performance (measured as the median proportion of resource collected over 20 independent simulation runs) of I-Swarms and B-Swarms of different sizes in the *Variable* scenario: (a) $N_R=20$, (b) $N_R=50$. Statistically significant differences between I-Swarm and B-Swarm performance in the same scenario are indicated with asterisks (Wilcoxon signed-rank test, ** p<0.01, * p<0.05). The average interquartile range was approximately 0.072.

of near-base congestion.

On the other hand, there were cases where recruitment did not improve foraging performance. Mineral desposits, for instance, were very hard to find for small swarms. B-Swarms needed to have at least 30 members before it was likely that they could find a deposit early enough to ensure that recruitment enabled them to outperform an I-Swarm. Moreover, while B-Swarms typically outperformed I-Swarms when foraging for Nectar, this did not hold for swarms of size $N_R=30$ and 50. Under these conditions, B-Swarms were not large enough to discover and exploit multiple groups of flowers in parallel, but were large enough to rapidly exhaust a single group of flowers by recruitment, ensuring that B-Swarms spent significant time returning to exhausted groups, and proportionately more time randomly searching rather than benefitting from recruitment. This unfortunate interplay between rapid exploitation of a group and insufficient exploration caused B-Swarms of 30 and 50 robots to perform similarly to I-Swarms of the same size.

Odometry error

Error in a robot's position estimation is an important influence on foraging performance where robots return to remembered deposits or are recruited to new ones. In this section, the value of the κ parameter (Equation 4), previously set to 0.005, is varied in order to explore the effect of odometry noise in the *Patchy* scenario (see Figure 5).

Confirming the previously presented results with low odometry noise, the B-Swarm outperformed the I-Swarm when $N_D=10$, and performed similarly or slightly worse than the I-Swarm when the number of deposits increased. Increasing κ did not affect the performance of either swarm when deposits were very easy to find $(N_D=100)$ and only slightly degraded the performance when $N_D=25$.

The impact of odometry error was most significant when 10 deposits were placed in the environment. While collective foragers could harvest significantly more resources than individualists when odometry error was low, the relative advantage of B-Swarms degraded as κ increased until it was extinguished or even slightly revered. This was an expected result, as the information about location of deposits that guided the B-Swarm robots became more erroneous with high κ , while individualist errors did not propagate to other robots in the I-Swarm, the performance of which was generally less affected by κ .

Interestingly, the impact of odometry noise on B-Swarm performance was stronger for 50-robot swarms than 20-robot swarms. While the performance of a 20-robot B-Swarm rarely fell below that of an equivalent I-Swarm even for high levels of odometry noise, 50-robot B-Swarms tended to perform worse than equivalent I-Swarms for moderate or high levels of odometry noise.

Even though robots in a 50-robot B-Swarm tended to recruit each other at a similar rate, the difficulty of finding advertised deposits when κ was high resulted in increased recruitment to deposits of low quality. For such swarms, the proportion of deposits within a higher-quality patch visited due to recruitment was 21% when $\kappa=0.01$, but only 13% when $\kappa=0.1$. Moreover, the distortion of information due to higher odometry error resulted in a smaller total amount of deposit collections (average of 76.9 visits per run when $\kappa=0.01$, but only 47.1 when $\kappa=0.1$).

In contrast, while increased odometry error also negatively affected the amount of times deposits were visited by a B-Swarm of 20 robots (average of 32.5 times per run when κ =0.01; 20.6 times when κ =0.1), the smaller swarm was able to switch to more individualist behaviour when robots failed to locate advertised deposits due to poor odometry: 52% of visited deposits were found by random walk and 33% by recruitment when κ =0.01, while 63% were found by random walk and only 23% by recruitment when κ =0.1.

On the other hand, in the larger 50-robot B-Swarm it was harder to behave like an individualist when odometry failed (34% of deposit visits were due to recruitment when $\kappa =$

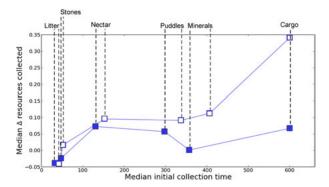

Figure 6: The relationship between the median time taken to collect the first resource and the difference between total resource collected by a B-Swarm and an I-Swarm in various scenarios. Data is shown for 20-robot swarms (solid symbols) and 50-robot swarms (open symbols).

0.01, with a very similar 31% due to recruitment when $\kappa = 0.1$) since a bigger group generated more ultimately fruitless recruitment. If at least one searching robot eventually found a deposit, this information propagated through the swarm, causing the robots to remain near the location and try to access the resource, generating wasteful congestion instead of allowing the resumption of potentially more useful random walk exploration.

Discussion

It is often difficult to intuitively predict the aggregate results or systemic properties of swarm behaviour because of the non-trivial nature of inter-robot interactions and interactions between robots and their environment. However, the analysis presented in this paper shows that it is possible to understand swarms by studying how they behave in various environments. Here we offer a set of generalised principles extracted from the experiments.

When To Forage Collectively

1. When resource is hard to find: B-Swarms performed better than I-Swarms in environments where deposits were harder to find but returned more resource. In particular, the advantage of recruitment was related to the difficulty of discovering deposits (Figure 6), but not to the length of a trip from a deposit to the base, at least within the scale of the scenarios simulated here. The B-Swarm advantage was more significant in larger swarms that covered the area faster and thus had a higher probability of discovering deposits. A small B-Swarm of 20 robots had difficulties, especially where deposit discoveries were rare and represented a small fraction of the total resource. These results suggest that communicating robots are useful for tasks like extracting rare minerals or retrieving lost cargo, but not for picking up litter from streets.

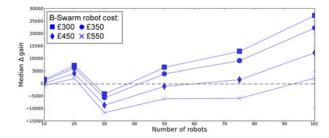

Figure 7: Projected relative gain from using B-Swarm rather than I-Swarm to collect *Nectar*, where the cost of an I-Swarm robot is £300, the gain from collecting all resources is £100,000, and the cost of a B-Swarm robot varies.

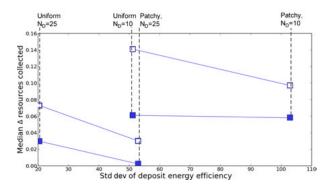

Figure 8: The relationship between the standard deviation of deposit energy efficiency and the performance difference between B-Swarms and I-Swarms. Data is shown for 20-robot swarms (solid symbols) and 50-robot swarms (open symbols). The B-Swarm advantage did not increase in the *Patchy* variant of each *Uniform* scenario.

2. When congestion is a problem: The performance of large swarms of individualists decreased rapidly as congestion around the base prevented robots from foraging. In contrast, recruited groups of B-Swarm robots could solve congestion problems near deposits in parallel with each other, increasing the amount of robots that could operate effectively near the base at the same time. It is notable that this B-Swarm feature would become less effective if the swarm size increased significantly, as the recruited groups would become larger and there would be more of them.

When Not To Forage Collectively

1. When resource is abundant: I-Swarms could slightly outperform B-Swarms when items were abundant and easy to find. Not only was recruitment in these environments unnecessary, but a combination of environmental and informational interference caused advertised locations to become depleted before a recruit could reach them, ensuring that recruitment incurred a performance cost.

- **2.** When reliablity of information is low: A decrease in the reliability of information about deposit locations due to odometry error caused the foraging ability of collective foragers to degrade significantly. In these cases, I-Swarm performance may be more reliable, although still generally poor.
- **3.** When deposits are very hard to find quickly: It was very difficult for small swarms of both types to find *Minerals* and *Cargo* where deposits were concentrated in a few distant locations. Despite the additional capabilities of the B-Swarm, once deposits were discovered there was not enough time to recruit others and exploit the location information.
- **4. Borderline cases:** In the real world, the cost of a robot swarm must be reasonable when assessed against the value generated by the foraging task. The additional investment required in order to equip robots with communication transmitters and receivers, and program them with the extended B-Swarm logic should thus be taken into account. For example, imagine that an I-Swarm robot costs £300 and that collecting all resources from the environment is worth £100,000. If the additional cost of a B-Swarm robot is £50, the effect of such an investment is not very dramatic (Figure 7). However, as communicating robots become more expensive, they are less able to return the extra investment.

Further Remarks

As currently implemented, B-Swarms were not better equipped than I-Swarms to selectively forage from more energy efficient deposits (Figure 8). Since B-Swarm robots were recruited to any deposit with an energy efficiency higher than the lowest known E_e , a large proportion of the swarm would collect from mediocre locations instead of exploring the environment. However, it was observed that unemployed B-Swarm robots could target higher E_e deposits as a consequence of receiving information from a large number of returning foragers. It is thus possible that the ability to preferentially exploit deposits with high E_e could be achieved by giving the robots a memory of previously encountered resources and an adaptive E_e threshold that would filter social information, as is the case in bees (Seeley, 1994). It would also be possible to implement a region of the robot base that acts as a dance floor in a beehive (Seeley, 1994; Wray et al., 2011), where robots would meet and compare advertised deposits in a more centralised fashion.

Robots designated for exploration would potentially also improve the performance of the swarm. It was shown that active scouting followed by rapid recruitment are very important factors in making bees so successful in dynamic environments (Granovskiy et al., 2012), compared to other social insects like ants (Ribeiro et al., 2009). Individual effects of the bee-inspired behaviours need to be explored in future experiments in order to establish their importance.

Conclusion

The ability of a simulated robotic swarm of individualist foragers and a swarm of collective foragers to harvect resources from various environments was compared. It was shown that recruitment is useful when resources are hard to find and are either clustered spatially or reward multiple visits, as the robots can spend relatively more time exploiting known deposits than exploring for new ones. On the other hand, the additional cost associated with building communicating robots may not be justified when there are many locations from which to gather resource or when the return expected from repeated visits to deposits is low. Furthermore, robots that rely on communication are more susceptible to errors when positional information looses reliability as may occur through odometry error.

Despite the tempting intuition that better or more expensive swarms will deliver better results, the question of whether to equip robots with the ability to communicate is not a trivial one. Just as natural evolution shapes species to become as simple but at the same time as effective as possible within their biological niche, engineered robots can benefit from our ability to step back and consider the nature of the tasks that they face.

Embodied Evolutionary Robotics with Large Number of Robots

Nicolas Bredeche^{1,2}

¹Sorbonne Universités, UPMC Univ Paris 06, UMR 7222, ISIR, F-75005, Paris, France ²CNRS, UMR 7222, ISIR, F-75005, Paris, France nicolas.bredeche@upmc.fr

Abstract

Embodied evolutionary robotics is a particular flavour of evolutionary robotics, where the evolutionary optimization of behaviours is achieved in an on-line and distributed fashion (Watson et al., 2002). The question asked in this paper is: does population size play a role in the evolution of particular behaviours? We experimentally demonstrate that varying the number of robots and the size of the environment can lead to very different outcomes in terms of evolved behaviours.

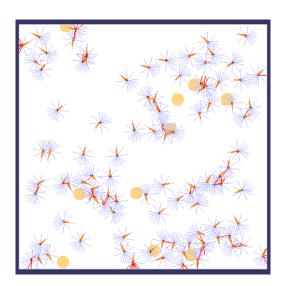

Figure 1: Experimental setup: a population of robots with 8 infra-red (IR) sensors (shown in blue) is deployed in an environment where 10 (yellow) landmarks are randomly placed. The robots are modelled after the famous e-puck robot, and communication between robots is achieved through the IR devices. The red tail is visible to the user only (used for identifying directions).

The mEDEA algorithm

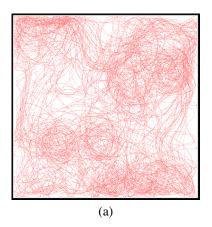

For this study, we use a particular algorithm that does not address any objective function, but rather perform environment-driven evolution. Similar to other works in artificial life, such as Tierra (Ray, 1991), medea favors individuals that are capable to spread their genomes in other individuals, without any explicit consideration for any user-defined task. medea has been extensively described elsewhere (Bredeche et al., 2012), and has been tested with up to 20 real robots.

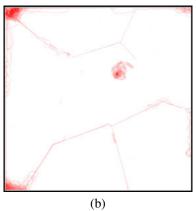

medea considers a set of robots with limited communication capabilities. Evolution relies on the diffusion of genomes from peer to peer, and genomes compete with one another to spread over the population of robots. To do so, each robot carries a genome, which defines its behaviour during a predefined amount of time (its "lifetime"). Whenever two robots are close enough, each transmits a mutated copy of its current genome to the other, and store the incoming genome in a list for further use. At the end of the robot's lifetime, the list of previously received genomes is emptied except for one arbitrarily selected genome, which is then mutated (using gaussian mutation) and replaces the genome used so far. Because the new genome is arbitrarily selected, there is pressure towards genomes that are able to drive their "vehicles" (i.e., the robots) to spread themselves over the population, favouring behavioural strategies better fitted to the environment.

Experiments

In a previous work (Bredeche et al., 2012), we showed that the average number of encounters is critical to survival, and is related to the number of robots, the communication radius and the size of the environment. That is: if robots get lost and end up with no new genomes to carry on evolution, the algorithm fails (ie. the robots do not survive).

The question addressed here is quite the opposite: given the population is large enough for the algorithm to work (ie. each robot will encounter at least one other robot during its lifetime), what happens when we consider larger populations? To answer this question, we consider experiments with different setups (units are given in pixels, a robot is 5x5 pixels): (1) Setup 1: 100 robots in a 400x400 environment; (2) Setup 2: 200 robots in a 1000x1000 environment; (3)

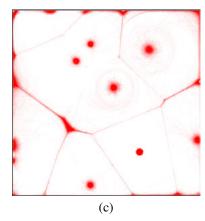

Figure 2: Trajectories from the last generations of three different setups (typical runs): (a) 100 robots, 400 x 400 environment; (b) 200 robots, 1000 x 1000 environments; (c) 4000 robots, 4000 x 4000 robots.

Setup 3: 4000 robots in a 4000x4000 environment.

The setup we consider is similar to what is shown in Figure 1 (see caption for description), except for the environment size and number of robots which vary wrt. the setups. We consider that each robot lives for 400 steps, during which it spreads its genome to every robots encountered. Each robot senses its surrounding with 12 infra-red sensors with limited range, which are also used for local communication (sending/receiving genomes), as well as a particular sensor which gives the direction and distance to the closest landmark (infinite range). There are 10 landmarks in the environment (initially placed at random locations). Landmarks provide no direct advantage nor disadvantage to nearby robots (ie. landmarks are a priori useless). Each robot is controlled by an Elman recurrent neural network with 5 neurons in the hidden layer, and the network weights are read from the genome.

Fig. 2 shows three typical examples from each of the three setups (at least 10 replications per setup have been done, each leading to similar results). These images show the trajectories of each of the robots over the last few generations of one run. Several conclusions can be drawn just from experimental observations.

Setup 1 displays randomly moving robots. This is an efficient behavioural strategy as each robot gets the opportunity to spread its own genome, while not being able to distinguish itself from others by doing so. Though a tendency to orbit around landmarks can be seen, this is far from the only behaviours observed, and behaviours from all robots are very similar with no clear clusters identified;

Setup 2 is rather different as three different behaviours can be observed: (1) some robots gather in corners (2) a group of robots is closely orbiting around one of the 10 landmarks and (3) some (few) robots appears to be travelling in straight lines.

Setup 3 provides a clear vision of what Setup 2 merely sketched: robots are either orbiting around landmarks, or

travelling in straight lines away from the landmarks. Also, very small groups are found orbiting around landmarks, but at some distance, avoiding interaction with the robots which are positioned right on the landmark (e.g. the landmark in the center).

These experiments show that increasing the number of robots and size of the environment leads to more diversity in the behaviours observed. However, the most compelling observation comes from robots travelling in straight lines, seemingly avoiding the landmarks. While it was not predicted *a priori*, this behaviour can be understood from observations: robots keep the farther away from any landmarks, resulting in clusters of robots travelling on the exact frontier between two landmarks. It is also interesting, if not useful, to note that this type of behaviour produces some kind of distributed voronoi tesselation, using landmarks as seeds.

Conclusion

The take-home message is that population size may dramatically change the results of evolution. In particular, the emergence of what resembles distributed Voronoi tesselation shows a striking example of what can only be observed when scaling up the population size.

One current limitation of this study it that population size and environment size were changed simultaneously, without considering the *density* of robots. This is currently under investigation.

Associating Nearby Robots to their Voices

Plamen Ivanov and Dylan Shell Texas A&M University, College Station, TX 77840 flame09@tamu.edu

Abstract

It can be useful for a robot in a team to recruit the help of others after considering their poses in space. When the initiating robot is aware of the network addresses (or IDs) of the robots it may ask for cooperation over the network. But if the initiating robot is ignorant of their IDs then it becomes rather more complex or time consuming. In this paper, robots use a simple visual (locally sensed) gesture (such as a light being turned on or off) in addition to wireless messages to quickly and effectively establish a one-to-one association between physical location IDs and wireless IDs. This paper identifies, describes, formalizes, and then generalizes the problem of establishing a local association between neighboring robots' physical location IDs (in the reference frame of an observing robot) and their wireless IDs. We describe three algorithms that solve this problem: two are deterministic algorithms and one is a probabilistic algorithm. Using the algorithms and formalism, we examine the structure underlying this association problem.

Introduction

Robots cooperating in teams often benefit from spatially referenced communication: "Would the robot to my left, please help me move this piano?" But many current implementations are influenced by the fact that practical perception of other robots is sensor-based (e.g., using vision via cameras) while communication is based on network technology (e.g., Wi-Fi, radios). Since the same robot will have different identifiers in these two realms, an association must be formed if our robot is to request help over the network: "Will robot 192.168.0.56 help move this piano?" We consider the problem of associating two independent channels of communication to form a one-to-one matching between sources in one channel and communication sources in the other.

We specifically consider the question of relating a robot with some relative pose (*i.e.*, when the "where" of the robot is known in the local frame) to a name which can be used to refer to that robot directly (*i.e.*, the "who" of that robot). The robots comprising the system are assumed to be able to interact through two independent communication channels. Using only these two channels and no global localization knowledge or global communication, all robots in the system must each solve:

For each robot "visible" in the second channel, determine and associate the appropriate network address in the first channel.

The many different variants of this problem are usually addressed by using an array of visual fiducials and a hand-crafted list of associations (Garrido-Jurado et al., 2014; Cassinis and Tampalini, 2007; Howard et al., 2004), or by initially calibrating and identifying the robots. These solutions are *ad hoc* and focus on practical cases of a specific variant of the problem (Mathews et al., 2010).

In terms defined by Støy (2001), the first channel in the motivating system is a non-situated channel, such as a Wi-Fi or radio, and the second channel is a situated communication channel, such as a light source attached to a robot. The capabilities of the situated visual channel are assumed to be minimal: a simple on/off communication strategy over the visual channel is enough to complete the association successfully. This could be implemented by moving the robot (e.g., performing a predefined wiggling repertoire), or switching on a light, or other such visually identifiable gesture (e.g., an instance of a protocol on just such a channel is given in Dieudonné et al. (2009)). The non-situated radio channel is assumed to have a message size which can at minimum fit the radio ID of a robot.

In this paper, we identify and formalize the problem generally, showing that it has an interpretation from an information filtering perspective (LaValle, 2009). Our paper describes two deterministic algorithms and a probabilistic algorithm solving this association problem, each having distinct features and drawbacks. The formalism and solutions are applicable to many circumstances in which indexical knowledge must be related to objective knowledge (Agre and Chapman, 1987; Lespérance and Levesque, 1994) because the former represents task relevant information—natural in the one channel—while the latter permits targeted transmission—a straight-forward operation in the other channel.

The generalized association problem impinges on questions of task representation, addressing, communication, and localization —each topics that are subtle and nuanced in their own right. For example, although in the motivating

piano moving scenario the indexical, task-relevant channel is the visual, situated channel, this need not be the case. Using this formalism we have made a step towards identifying and understanding the subtleties involved.

Related Work

Practically speaking, marker systems are limited in the number of unique identifiers which can be encoded, suffer from reliability issues of correctly identifying markers, have restrictions on the maximum distance at which markers can be identified and in what environments they can be deployed, and have significant hardware and software requirements (Garrido-Jurado et al., 2014; Cassinis and Tampalini, 2007). Solutions that require calibration of global knowledge are especially undesirable as system size increases.

The idea of *spatially targeted communication* in Mathews et al. (2010) and the model and solutions they use have similarities with the model and solutions we describe. However, their approach is only a solution for a pair of robots in the system. The model lends itself to analysis through the extinction probability of a branching processes (Haccou et al., 2007); we return to discuss this means of analysis later. Dieudonné et al. (2009) present a multi-robot system in which robots are indistinguishable from each other and there is no explicit means of communication. Their approach is remarkable because it considers a weak synchronicity model, but it makes strong sensing assumptions, precluding use in most real robot settings.

Mutual or collective localization in a multi-robot system (e.g., Franchi et al. (2009); Fox et al. (2000)) is related to the association problem presented in this paper because a global metric reference frame provides unique labels for each robot. Oftentimes, however, the cost of localizing all the robots is greater than one wishes to pay merely for targeted communication.

Problem Definition and Formalism

In this section we give a precise description of the multirobot system and the problem which we address.

Motivating System

Consider a multi-robot system composed of n robots, which are spread arbitrarily across an environment. Each robot in the system can directly observe and distinguish from the environment some nearby robots using a camera. Robots can also flash a light on and off. The camera and light form a single bit communication channel — the **camera channel**. Each robot can also directly communicate through messages over a **wireless channel** with robots in range. Each robot has a **wireless ID** and itself assigns **location IDs** (for example, local range and bearing pairs) to robots it can recognize through its camera.

Every robot starts knowing n and the IDs of robots they can receive messages from in either of the channels. The robots have no knowledge of which wireless ID is assigned

to which robot. The operation of the robots is modeled with synchronous, discrete time steps. Both channels have a limited transmission range *i.e.*, a robot is unable to receive messages from all robots in the system directly.

The goal is for each robot to form a one-to-one association between the location IDs of robots in the camera channel and the wireless IDs of robots in the wireless channel.

Generalized Formal Specification

A generalized formal definition of the problem follows. Graphs representing the system are depicted in Fig. 1.

Definition 1. We model a multi-robot system that has one radio communication channel (channel 1) and one physically situated communication channel (channel 2) with the tuple: $\langle G_1 = \langle V, E_1 \rangle, G_2 = \langle V, E_2 \rangle, C_1, C_2, f_1, f_2 \rangle$ where

- 1. V is a set of vertices, each representing a robot.
- 2. $G_1 = \langle V, E_1 \rangle$ and $G_2 = \langle V, E_2 \rangle$ are two directed graphs representing the connectivity of the system of robots over the two communication channels,
- 3. $E_1 \subseteq V \times V$ has directed edges s.t. $e \equiv (v_i, v_j) \in E_1$. This is interpreted as robot i being able to receive a one-hop message from robot j over channel 1,
- 4. $E_2 \subseteq V \times V$ is analogous, but for channel 2,
- 5. $E_2 \subseteq E_1$ this is the channel **inclusion property**, stating that if i can receive a channel 2 message from a robot then it is guaranteed to be able to receive a channel 1 message from that robot too,
- 6. f_1 , f_2 are labeling functions of the form $f: V \times V \mapsto C$ which are applied to channels 1 and 2, respectively.
- 7. C_1 and C_2 are the label sets for channels 1 and 2.

Each channel has an associated labeling function and the set of labels correspond to addresses (wireless IDs and location IDs, respectively). In the motivating system, the labeling functions will provide unique IDs for the wireless channel (IP addressed) and locally unique IDs (defined precisely, next) for the location channel. The labeling functions are not known to the robots. The only requirement is that whatever procedure makes the ID assignment does not violate the following property:

Property 1. Labeling functions have:

$$\forall x, y, z \in V, e_y = (x, y) \in E_{ch} \land e_z = (x, z) \in E_{ch} \Rightarrow f_{ch}(e_y) \neq f_{ch}(e_z).$$

Property 1 ensures that each neighborhood will have non-repeating IDs, which we call *locally unique IDs*. In the motivating system, it applies to the location IDs. It also holds for global IDs which are not locally in conflict *i.e.*, no individual robot will see the same wireless ID broadcasted by two different robots in its wireless neighborhood. Note that any labeling that provides unique IDs satisfies property 1.

To examine an individual robot's perspective we introduce several additional concepts.

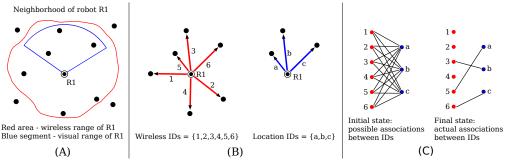

Figure 1: This figure presents a view of a local neighborhood around a robot in a multi-robot system (A) and some of the graphs which are associated with the channel association problem (B),(C). The wireless communication channel (in red) connects robot R1 to some of the robots surrounding it. The camera communication channel (in blue) has a more restricted view of robots in the system. Robot R1 is only aware of the set of IDs which correspond to the connection edges of each channel. The robot represents its knowledge of the association between IDs as a bipartite graph as shown in (C).

Definition 2. A neighborhood is a subset of the system centered on an individual robot i. A neighborhood can be described by the tuple $\langle V^i, E_1^i, E_2^i, f_1, f_2, C_1^i, C_2^i \rangle$ where

- 1. i indicates the robot centered in the neighborhood,
- 2. V^i consists of robots for which a directed edge $e \equiv (v_i, v_j) \in E_1$ exists,
- 3. E_1^i and E_2^i contain all directed edges in E_1 and E_2 which have robot i as source.
- 4. C_1^i , C_2^i are the labels given to edges in E_1^i and E_2^i by f_1 and f_2 , respectively.

Definition 3. The **local view** of robot i is the information directly available to the robot. It can be described by the tuple $\langle n, C_1^i, C_2^i, O^i = \langle O_1^i, O_2^i, ... O_t^i \rangle \rangle$ where

- 1. n is the maximum possible robots in the entire system,
- 2. C_1^i and C_2^i are label sets as previously defined,
- 3. $O^i = \langle O_1^i, O_2^i, ... O_t^i \rangle$ is a sequence of observations (Def. 5) of the robots in the neighborhood of i, and t is the time step during which an observation was made.

Definition 4. An activation captures the ground truth of the communication state of a neighborhood for a given time step t, described by the tuple $A_t^i = \langle C_{1At}^i, C_{2At}^i \rangle$ where

- 1. C_{1At}^i is the set of labels of robots which are in range of and from which a message was sent to robot i on channel 1 during time step t,
- 2. C_{2At}^i is defined similarly for channel 2.

Definition 5. An observation is an individual robot's perception of an activation for a given time step t and is described by the tuple $O_t^i = \langle C_{1Ot}^i, C_{2Ot}^i \rangle$ where

- 1. C_{1Ot}^i is the set of labels of robots from which a message was received by robot i on channel 1 during the time step,
- 2. C_{2Ot}^i is defined similarly for channel 2.

Given the assumptions about no failure and no interruption in messages, activations and their corresponding observations are identical.

Definition 6. Each robot maintains an **information state**, or **i-state**, which represents the current knowledge the robot

has about its neighborhood. The i-state is described by the bipartite graph $S^i = \langle C_1^i, C_2^i, E_{1-2} \rangle$ where

- 1. C_1^i and C_2^i are label sets as previously defined and represent the two distinct vertex sets of the graph,
- 2. E_{1-2} is the edge set of the graph and represents possible associations between elements from each label set.

Each robot starts in complete ignorance of the actual oneto-one association of labels. As observations arrive, it updates its i-state by removing edges from the graph.

Definition 7. The **one-to-one association problem** for each robot *i* is:

<u>Input</u>: a local view with an observation sequence,

Output: a complete or partial one-to-one association between channel 1 labels and channel 2 labels for the label tuple $\langle C_1^i, C_2^i \rangle$ corresponding to i's neighborhood.

Algorithms to Solve the Association Problem

In this section we present three algorithms that can be used to achieve the one-to-one association problem in a multirobot system. The algorithms operate for a system with the following properties:

- 1. There are no communication failures, lost messages or message degradation.
- 2. The channel inclusion property holds.
- 3. The minimum message size for the wireless channel is $\log_2{(n)}$ bits.
- 4. The message size for the visual channel is 1 bit.
- Every robot can receive and process messages from any number of robots in each channel during a given time step.
 Robots can only send one message in each channel during a given time step.

A **listener** is a robot from whose perspective we are analyzing the system. A **message pair** consists of the transmission of a message in each channel by a given robot during the same time step. The earlier assumption that each listener begins knowing the number of robots it can receive messages from in each channel can be achieved by having a single time step in which every robot transmits a message pair.

Naïve Algorithm.

In the Naïve algorithm, every robot emits a visual message during the time step which is equivalent to the robot's wireless ID. A listener simply fills a table associating a wireless ID to a location ID which is currently active. The pseudo code for this algorithm can be seen below.

Algorithm 1 Naïve Algorithm

```
procedure Naïve

matchTable 
ho [wireless ID, location ID] pairs

for t \leftarrow 1, n+1 do 
ho For each possible wireless ID

if t-1 == myID then

broadcast(visualMessage)

end if

if messagesReceived() then

if local\_robot.isActive() then

pair \leftarrow [t-1, locationID]

matchTable.add(pair)

end if

end for
end procedure
```

Logarithmic Algorithm

In the Logarithmic algorithm the fact that n identifiers can be represented with $\log_2{(n)}$ bits is used. The listener associates each observable robot with an array of size $\log_2{(n)}$. At time step t, all robots whose t^{th} bit is equal to 1 will emit a visual message. After each time step a listener can fill one more bit in the array of bits corresponding to the wireless IDs of the visually active robots. The pseudo code is below.

Algorithm 2 Logarithmic Algorithm

```
1: procedure LOGARITHMIC
        self\_bit\_arr \leftarrow to\_bit\_array(my\_ID)
 3:
        table\_arr \leftarrow array[num\_neighbors][log_2(n)]
 4:
        for t \leftarrow 1, \log_2(n) + 1 do
             if self_bit_arr[t-1] == 1 then
 5:
                 broadcast(visualMessage)
 6:
 7:
             end if
 8:
            for i \leftarrow 0, num_neighbors do
 9:
                 if neighbor[j].isActive() then
10:
                     table\_arr[t][j] = 1
11:
                 end if
12:
             end for
13:
         end for
14: end procedure
```

Probabilistic Algorithm

In the Probabilistic algorithm all robots construct an $h \times s$ i-state matrix to represent their i-state. Here h represents the number of robots in direct communication over channel 1 (C_1^i from S^i) and s – the number of robots over channel 2 (C_2^i from S^i). The i-state starts filled with 1's, which indicates complete ignorance of the one-to-one associations. Each cell in the i-state matrix corresponds to an edge in E_{1-2} from S^i . The wireless IDs (labels) of all robots that are within communication range are associated to an activity array (C_{1Ot}^i from O_t^i) that keeps track of which robot

transmitted a message in the current time step (1 is used to denote a transmission). Each wireless ID is given an index $w \in [0,h-1]$. Similarly, the location IDs are associated with an activity array $(C_{2Ot}^i \text{ from } O_t^i)$. Each location ID is given an index $l \in [0,s-1]$. At any moment the i-state matrix contains the listener's current information about the matching between wireless IDs and location IDs.

During each time step, each robot emits a message pair with 50% probability. Every listener fills in an $h \times s$ observation matrix, which captures an observation of the neighborhood made during the current time step. This matrix is filled based on the following principle: The [w][l] entry in the observation matrix is filled with a 1 if both the w^{th} wireless ID and l^{th} location ID were active during the current time step. All other entries are filled with 0's.

Once the observation matrix has been constructed it is used to update the i-state matrix of the listener. All [w][l] entries from the observation matrix for which either the w^{th} wireless ID or l^{th} location ID have been active in the current time step are multiplied with the corresponding i-state matrix entries. This produces a new i-state matrix.

Once the i-state matrix contains only s 1's, the one-to-one association problem for the listener and its neighborhood is complete. The non-zero [w][l] entries tell us that the w^{th} wireless ID and the l^{th} location ID belong to the same robot.

Pseudo code appears in **Algorithm 3**, and an i-state and observations for a single run of the algorithm for one neighborhood are depicted in Fig. 2.

Algorithm 3 Probabilistic Algorithm

```
1: procedure Probabilistic
 2:
        broadcast(messagePair)
 3:
                                  > number of wireless IDs in range
 4:
                                  ⊳ number of location IDs in range
 5:
        istate[h][s] \leftarrow 1's
 6:
        observ[h][s]
 7:
        wifi\_activity[h]
                                             ⊳ 0 - inactive, 1 - active
 8:
        vis\_activity[s]
                                             \triangleright 0 - inactive, 1 - active
 9:
        for each time step do
10:
            if fairCoinFlip() then
                broadcast(messagePair)
11:
12:
            wifi\_activity \leftarrow receivedWifiMsqs()
13:
14:
            vis\_activity \leftarrow receivedVisMsgs()
            observ \leftarrow fillObs(wifi\_activity, vis\_activity)
15:
16:
            istate \leftarrow updateState(observ)
            if istate.isFinal() then
17:
18:
                ready \leftarrow TRUE
19:
            end if
20:
        end for
21: end procedure
```

Information Space Interpretation

Although only the probabilistic algorithm explicitly uses the idea of an information space, both deterministic algorithms have an information space interpretation. In this section we examine the information space explored by the algorithms.

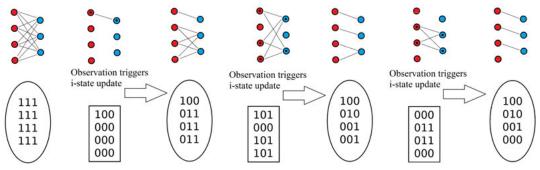

Figure 2: An i-state path through the transition graph. Here we can see the i-state of the robot (the matrices in ovals) and its progression as the robot makes observations (the matrices in squares). Bipartite graphs corresponding to each i-state and observation appear at the top.

Structure of Individual I-States and Observations

As observations about the neighborhood are made, a listener can update its i-state accordingly. The initial i-state is an $h \times s$ complete bipartite graph. An observation partitions the i-state bipartite graph into active and inactive vertices. All edges between an active and inactive vertex are eliminated from the i-state graph. The partitioned vertices form bipartite sub-graphs. Once such a partitioning occurs, the listener has reduced the potential associations between wireless IDs and location IDs. Every subsequent observation can split the already existing partitions further.

An observation can partition the vertices in such a way that it brings no additional information about the neighborhood. There are two observations which always bring no information: all robots are active or no robots are active. These are the zero-information observations. Observations can be paired based on symmetry – the partitioning these pairs induce on the i-state bipartite graph is the same.

The final i-state is a disconnected bipartite graph which is composed of bipartite sub-graphs of size 2 or 1. The sub-graphs of size 2 indicate a one-to-one association between a wireless ID and a location ID while the sub-graphs of size 1 show that a wireless ID belongs to a robot which cannot be observed by the listener.

The number of i-states for a given neighborhood is finite and can be found by calculating Bell's number for a set of size h. Bell's number counts the number of ways a set of a given size can be partitioned in.

The number of observations for a given neighborhood is 2^h . Since we have assumed an activation probability for a robot to be 50% (during the probabilistic algorithm), all neighborhood activations and corresponding observations have the same probability of occurring.

I-State Transition Graph

The i-states and observations for a given neighborhood form the **directed i-state transition graph**. The i-states form the vertex set of the transition graph and the directed edges correspond to the set of observations which lead from one i-state to another. A version of the transition graph can be seen in Fig. 3. The figure shows all i-states for a 4×3 neighbor-

hood (4 wireless IDs and 3 location IDs), all i-state to i-state transitions, and the number of observation for each transition.

The graph highlights properties of the i-state space:

- 1. The i-states can be grouped into several categories based on the number of partitions of the initial i-state bipartite graph they contain. We call these categories **levels**. There are h levels in each transition graph corresponding to same size partitions of the graph S^i . The initial i-state is at level 1 (trivial partition of the graph S^i), and the final i-state is at level h (there are h partitions of the graph S^i). Any intermediate level will have between 2 and h-1 partitions of S^i .
- At each next level the number of zero-information states doubles.
- 3. At each level the transition probability is equal for all transitions (for the probabilistic algorithm).
- 4. Each i-state can transition to itself (through zero-information observations).
- 5. There are no transitions between i-states from a higher partition level to a lower partition level and inside a level (with the exception of self-transitions).

Deterministic Algorithms and the I-State Graph

The Na $\ddot{\text{u}}$ ve algorithm uses only observations resulting from a single active robot. This restricts the paths through the transition graph to a subset of the 1-level transitions. The Logarithmic algorithm, on the other hand, allows any n-step path through the transition graph. The specific path for both algorithms is predetermined once a neighborhood is formed.

Algorithm Performance Analysis

After examining the information space we can examine the performance of the three algorithms presented earlier.

Naïve Algorithm

The Naïve algorithm runs for n time steps, where n is the number of unique IDs that can be used by the system of robots. The algorithm runs for n time steps regardless of how many of the n identifiers are in use by actual robots. Every agent emits only one message during the execution of this algorithm – at most n for the entire system.

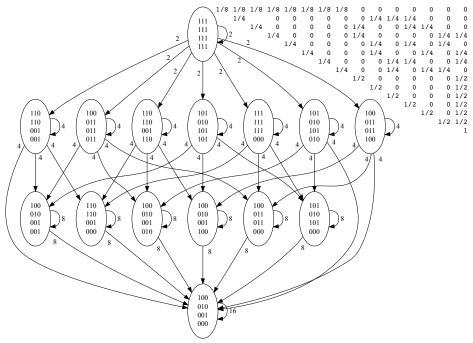

Figure 3: I-state transition graph and corresponding transitional probability matrix for the case of h=4 wireless, s=3 location IDs. Each graph node contains an $h \times s$ state matrix and each edge is labeled with the number of observations which trigger the given transition.

Logarithmic Algorithm

The Logarithmic algorithm runs for $\log_2{(n)}$ time steps and generates at most $\frac{1}{2}n\log_2{(n)}$ messages. This is due to the fact that at most half of all robots will emit a message pair at each time step, since only half of all possible unique IDs will have a 1 in their i^{th} bit.

Probabilistic Algorithm

The one-to-one association problem for a neighborhood of size $h \times s$ has a lower bound of $ceil(\log_2{(s)})$ time steps. The best case scenario for the association problem occurs when each observation made by the listener splits all current partitions of the i-state bi-graph S^i evenly.

Due to the probabilistic nature of this algorithm, its overall analysis is not straightforward and a closed-form solution for its expected running time has not been discovered.

Mathews et al. (2010) present a probabilistic algorithm which can be modeled as a branching process and show an approximate upper bound for the mean of the expected time. Robots participating in the algorithm solving this model "die-off". The authors emphasize the difficulty in finding a closed form solution for the probability density function of the process.

We were unable to apply this model to the more general system we present here. The difficulty arises from successfully identifying elements of our model which can be regarded as "individuals" in a population which can be discarded (produce zero offspring).

Another approach is to use the **transition probability matrix** corresponding to the directed i-state transition graph.

The graph has the necessary properties of an absorbing Markov chain (Grinstead and Snell, 1997) — it has an absorbing state (the final state) and this state can be reached from any other state in the graph (transient states). See Fig. 3 for an example of the transition probability matrix. The expected number of steps from any state to reaching the final state can be calculated using the following formula:

$$\mathbf{t} = (I - Q)^{-1} \mathbf{1} \tag{1}$$

Here Q is a $t \times t$ matrix containing all transient to transient transition probabilities, \mathbf{t} denotes a vector of size t, I is the identity matrix, and $\mathbf{1}$ is a column vector of all 1's. The i^{th} element of \mathbf{t} gives the average expected number of steps to absorption if the process started from the i^{th} transient state. Thus, Eq. (1) can be used to calculate the expected running time to complete the one-to-one association problem for a given neighborhood.

This approach, however, is prohibitively expensive for all but the smallest values of h. As was noted earlier, the number of i-states (t) for a given neighborhood is given by Bell's number: B_h . Berend and Tassa (2010) give an upper bound of Bell's number which is O(h!) and $O(2^h)$. A simple application of all possible observations to all possible i-states can generate the matrix in $O(2^hB_h)$ time. The matrix inversion needed in Eq. (1) will take $O(B_h^3)$. The absorbing Markov chain method, therefore, runs in $O(h!^3)$.

A third approach is to simulate the running of the algorithm and gather statistical data. This was done by simulating activations of a neighborhood and running the Probabilistic algorithm until a one-to-one association was made

or a threshold was reached. Each neighborhood was run between 50,000 and 100,000 times. We simulated all neighborhood size combinations of $h \in [2,85]$ and $s \in [1,h-1]$. To validate the date from the simulation we also calculated the precise expected value for all combinations of $h \in [2,8]$ and $s \in [1,h-1]$ using the absorbing Markov chain approach. The absorbing Markov chain method results matched the simulation results up to the precision we used during the calculations (0.0001 time steps).

The results from the simulation trials of neighborhoods up to size 40 can be seen in Fig. 4, the remaining trial data is omitted to keep the figure more readable.

The results from the simulation can be informally approximated (further work is needed to get a good fit for the data) by the following two functions which give the expected time steps to complete the one-to-one association problem:

- 1. $2\log_2(h)\log_2(s+1)$
- 2. $\operatorname{arsinh}(hs)$

Using the first function, we can approximate the number of expected messages a given robot will emit: $0.5 \times 2\log_2{(h)}\log_2{(s+1)}$. The h and s would be based on the longest lasting neighborhood the robot participates in and assumes that the robots stop transmitting messages once all their neighbors inform them that they have completed the one-to-one association. For a dynamic system, this assumption would not be true and the robot may continue transmitting messages after the initial association has been completed.

Algorithm Comparison

The two deterministic algorithms have a performance which is dependent on the global size of the system. They also provide an exact execution time for the one-to-one association problem. The Naïve algorithm gives us the slowest performance but uses the least amount of messages. The Logarithmic algorithm is faster than the Naïve one but requires an increase in the number of messages used. The two deterministic algorithms also require very minimal use of the wireless channel (only used during the first system wide transmission, which is not strictly required for the Logarithmic algorithm).

The probabilistic algorithm does not depend on the global size of the system. Every robot can quickly achieve the one-to-one association for its neighborhood. This algorithm has the disadvantage that it has no guaranteed time expectancy. The overall performance of the system is dependent directly on the types of neighborhoods that compose it so an analysis of the robot distribution may be required before choosing this algorithm.

Relaxing Assumptions and Extending the Formalism

In this section we discuss relaxing some of the assumptions introduced in the course of the paper. We show that after

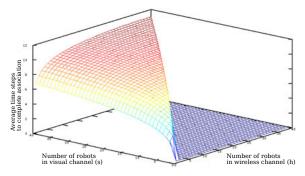

Figure 4: This is a plot of the average number of time steps to complete the association problem for all $h \times s$ neighborhoods for which $h \in [2,40]$ and $s \in [1,h-1]$. Every neighborhood was simulated between 50,000 and 100,000 times to obtain the results

relaxing these assumptions the formalism still applies and the algorithms can still be used with minor modifications.

We have assumed that robots operate in an environment with no noise, communication errors or failures. This assumption guarantees that when a robot sends a message it is always received. This results in edges in the i-state (possible associations) being either 0 or 1. If we allowed noise, communication errors and failures, an observation may carry false positives or false negatives. The formalism and probabilistic algorithm can still handle this case. However, instead of a 0 or 1 stored as a possible association between two IDs, an appropriate statistical measure is computed and stored for each possible association. This makes the bipartite graph representing an i-state a weighted one. The finite information space interpretation presented in this paper is not directly applicable to this case.

The channel inclusion property imposes restrictions on how the coverages of the communication channels are related. The assumption in this paper guarantees that a robot's continued observation will result in an i-state in which all robots in visual (channel 2) range will be matched to robots in wireless (channel 1) range. This restricts the possible final i-states. If the assumption is relaxed fully, the resulting final i-state may be an empty i-state (a fully disconnected bipartite graph) indicating that the sets of robots in each channel are completely disjoint. The formalism will still correctly represent the system. Perhaps more surprisingly, all three algorithms correctly handle this situation with no modification other than a modified stopping condition.

We specify that there are two communication channels. The addition of more channels can be beneficial for the Probabilistic algorithm, as it can partition the i-state bipartite graph faster. This, however, would require the i-state's dimensions to grow as the number of channels. In this work we have not pursued any analysis on the impact on performance that the addition of channels will have.

The visual channel is assumed to be a binary channel. If the visual channel can distinguish between several colors, as done in (Mathews et al., 2010), the effective bit-rate of the visual channel increases as the color can be used to pass additional information. For example, the message pair can contain a colored bit in the visual channel and a color label in the broadcast channel. This will result in a faster partitioning of the i-state bipartite graph.

Property 1 allows robots communicating through a communication channel to share IDs. For example, a system in which robots are guaranteed to not move in a way that will bring two duplicate IDs in the same neighborhood can operate with no conflicts. A system where positions can change arbitrarily will require the stricter unique ID requirement. If an outside reference, such as geographical data or some environmental property, is used to assign IDs a system can have some reuse of IDs and a guarantee that a conflict will not occur.

Conclusion

In this paper we consider an association problem between IDs in two independent communication channels in a multirobot system. The first channel is a radio channel which carries indexical knowledge about the robots while the second channel is a situated one and carries objective knowledge about the robots. Robots in the system need to make a one-to-one association between the two types of IDs as a preprocessing step to solving system tasks.

We provide a detailed formal description of the system and examine its properties from an information filtering perspective. We also show that this problem can be solved quickly and without the need for global localization knowledge and global communication by describing and analyzing two deterministic and one probabilistic algorithms.

The analysis of the probabilistic algorithm showed us that a closed-form solution for the expected performance of the algorithm based on the absorbing Markov chain is prohibitively expensive and that the applicability of another — based on branching processes — is uncertain but needs to be considered in more depth. We provide simulation results and give two functions which provide an informal approximation to the algorithm's performance. We compare the three algorithms and show that each has its advantages and drawbacks, relating to speed of execution, messages sent and communication channels used.

Lastly, we examined the ability of the formalism and algorithms we described to handle more realistic scenarios by relaxing some simplifying assumptions made during the creation of the formalism and analysis of the algorithms.

One future extension of this work is to examine in more detail the applicability of branching processes to the system model defined in this paper. Another extension is to analyze the performance of the algorithms after some assumptions, such as no communication failures, have been relaxed. A third extension is finding a better fit to the simulation data which can be used to predict the behavior of larger multirobot systems operating under the probabilistic algorithm.

Université de Lorraine, INRIA, Campus scientifique BP 239 Vandoeuvre-lès-Nancy Cedex, F-54506, firstname.lastname@loria.fr

Abstract

In this paper, we study the impact of selection methods in the context of on-line on-board distributed evolutionary algorithms. We propose a variant of the mEDEA algorithm in which we add a selection operator, and we apply it in a task-driven scenario. We evaluate four selection methods that induce different intensity of selection pressure in a multi-robot navigation with obstacle avoidance task and a collective foraging task. Experiments show that a small intensity of selection pressure is sufficient to rapidly obtain good performances on the tasks at hand. We introduce different measures to compare the selection methods, and show that the higher the selection pressure, the better the performances obtained, especially for the more challenging food foraging task.

Introduction

Evolutionary robotics (ER) (Nolfi and Floreano (2000)) aims to design robotic agents' behaviors using evolutionary algorithms (EA) (Eiben and Smith (2003)). In this context, EA's are traditionally seen as a tool to optimize agents' controllers w.r.t to an explicit objective function (fitness). This process is carried out in an off-line fashion; once the behavior is learned and the controller optimized, the agents are deployed and their controllers' parameters remain fixed.

On the other hand, on-line evolution (Watson et al. (2002)) takes a different approach in which behavior learning is performed during the actual execution of a task. In these algorithms, learning or optimization is a continuous process, *i.e.* robotic agents are constantly exploring new behaviors and adapting their controllers to new conditions in their environment. Usually, this is referred to as adaptation.

These two visions of ER can be related to on-line and offline approaches in Machine Learning (ML). Off-line ML algorithms learn a specific task and solutions should generalize to unseen situations after the learning process, whereas on-line ML algorithms progressively adapt solutions to new presented situations while solving the task. In this sense, both on-line ML algorithms and on-line EA's perform lifelong adaptation or learning, to possibly changing environments or objectives. In this paper, we focus on on-line distributed evolution of swarm robotic agents. We are interested in learning individual agents behaviors in a distributed context where the agents adapt their controllers to environmental conditions independently while deployed. These agents may locally communicate with each other and do not have a global view of the swarm. In this sense, this approach finds many ties with Artificial Life, where the objective is to design autonomous organisms that adapt to their environment.

On-line distributed evolution may be viewed as distributing an EA on the swarm of agents. Traditional evolutionary operators (mutation, crossover etc.) are performed on the agents and local communication ensures the spread of genetic material in the population of agents.

In EA's, selection operators drive evolution toward fit individuals by controlling the intensity of selection pressure to solve the given task. These operators and their impact on evolutionary dynamics have been extensively studied in off-line contexts (Eiben and Smith (2003)). In this paper, we study their impact in on-line distributed ER, where evolutionary dynamics are different to the off-line case: selection is performed locally on partial populations and fitness values on which selection is performed are not reliable. Our experiments show that, in this context, a strong selection pressure leads to the best performances, contrary to classical approaches in which lower selection pressure is preferred, to maintain diversity in the population. This result suggests that, in distributed ER algorithms, diversity is already maintained by the disjoint sub-populations.

Several authors have addressed on-line evolution of robotic agent controllers in different contexts: adaptation to dynamically changing environments (Dinu et al. (2013)), parameter tuning (Eiben et al. (2010)), evolution of self-assembly (Bianco and Nolfi (2004)), communication (Pineda et al. (2012)), phototaxis and navigation (Karafotias et al. (2011), Silva et al. (2012)). Some of this work is detailed in the next section. The authors use different selection mechanisms inducing different intensities of selection pressure to drive evolution. In this paper, we compare different selection operators and measure the impact they have on the

performances of learning two swarm robotics tasks: navigation with obstacle avoidance and collective food foraging.

We begin by reviewing different selection schemes proposed in the context of on-line distributed ER and then we present the algorithm that will serve as a test bed, along with the selection methods we compare. In the fourth section, we detail our experimental setting and discuss the results. Finally, we close with some concluding remarks and future directions of research.

Related Work

In the following, we review several on-line distributed ER algorithms and discuss the selection mechanisms that were applied to ensure the desired intensity of selection pressure in order to drive evolution.

A common characteristic of on-line distributed ER algorithms is that each agent has one controller at a time, that it executes (the active controller), and locally spreads altered copies of this controller to other agents. In this sense, agents have only a partial view of the population in the swarm (a local repository). Fitness assignment or evaluation of individual chromosomes is performed by the agents themselves and is thus noisy, as different agents evaluate their active controllers in different conditions. Selection takes place when the active controller is to be replaced by a new one from the repository.

PGTA (Probabilistic Gene Transfer Algorithm) introduced by Watson et al. (2002), is commonly cited as the first implementation of a distributed on-line ER algorithm. This algorithm evolves the weights of fixed-topology neural controllers and agents exchange parts (genes) of their respective chromosomes using local broadcasts. The algorithm considers a virtual energy level that reflects the performance of the agent's controller. This energy level increases every time the agents reach an energy source and decreases whenever communication takes place. Furthermore, the rate at which the agents broadcast their genes is proportional to their energy level and conversely, the rate at which they accept a received gene is inversely proportional to their energy level. This way, selection pressure is introduced in that fit agents transmit their genes to unfit ones.

Silva et al. (2012) introduced odNEAT, an on-line distributed version of NEAT (Neuro-Evolution of Augmenting Topologies) (Stanley and Miikkulainen (2002)), where each agent has one active chromosome that is transmitted to nearby agents. Collected chromosomes from other agents are stored in a local repository within niches of species according to their topological similarities, as in NEAT. Each agent has a virtual energy level that increases when the task is performed correctly and decreases otherwise. This energy level is sampled periodically to measure fitness values and, whenever this level reaches zero, the active chromosome is replaced by one in the repository. At this point, a species is selected based on its average fitness value, then a chro-

mosome is selected within this species using binary tournament. Each agent broadcasts its active chromosome at a rate proportional to the average fitness of the species it belongs to. This, added to the fact that the active chromosome is selected from fit niches, maintains a certain selection pressure toward fit individuals.

EDEA (Embodied Distributed Evolutionary Algorithm) (Karafotias et al. (2011)), was applied to different swarm robotics tasks: phototaxis, navigation with obstacle avoidance and collective patrolling. In this algorithm, each agent possesses one chromosome, whose controller is executed and evaluated on a given task. At each iteration, agents broadcast their chromosomes alongside with their fitness to other nearby agents with a given probability (fixed parameter). Upon reception, an agent selects a chromosome from those collected using binary tournament. This last chromosome is then mutated and recombined (using crossover) with the current active chromosome with probability $\frac{f(x')}{s_c \times f(x)}$, where f(x') is the fitness of the selected chromosome, f(x)is the fitness of the agent's current chromosome and s_c is a scalar controlling the intensity of selection pressure. To ensure an accurate measure of fitness values, agents evaluate their controllers for at least a minimum period of time (maturation age), during which agents neither transmit nor receive other chromosomes.

With mEDEA (minimal Environment-driven Distributed Evolutionary Algorithm), Bredeche and Montanier (2010) address evolutionary adaptation with implicit fitness, *i.e.* without a task-driven fitness function. The algorithm takes a gene perspective in which successful chromosomes are those that spread over the population of agents and which requires: 1) to maximize mating opportunities and 2) to minimize the risk for agents (their vehicles).

At every time step, agents execute their respective active controllers and locally broadcast mutated copies of the corresponding chromosomes. Received chromosomes (transmitted by other agents) are stored in a local list. At the end of the execution period (*lifetime*), the active chromosome is replaced with a randomly selected one from the agent's list and the list is emptied. An agent dies if there are no chromosomes in its list (if it did not meet other agents) and it remains dead until it receives a chromosome from another agent passing by.

The authors show that the number of living agents rises with time and remains at a sustained level. Furthermore, agents develop navigation and obstacle avoidance capabilities that allow them to better spread their chromosomes. This work shows that environment-driven selection pressure alone can maintain a certain level of adaptation in a swarm of robotic agents. A slightly modified version of this algorithm is used in this work and is detailed in the next section.

Noskov et al. (2013) proposed MONEE (Multi-Objective aNd open-Ended Evolution), an extension to mEDEA adding a task-driven pressure as well as a mechanism (called

market) for balancing the distribution of tasks among the population of agents, if several tasks are to be tackled. Their experiments show that MONEE is capable of improving mEDEA's performances in a collective concurrent foraging task, in which agents have to collect items of several kinds.

The authors show that the swarm is able to adapt to the environment (as mEDEA ensures), while foraging different kinds of items (optimizing the task-solving behavior). In this context, each type of item is considered a different task. The algorithm uses an explicit fitness function in order to guide the search toward better performing solutions. The market mechanism, which takes into account the scarcity of items, ensures that agents do not focus on the most frequent kind of items (the easiest task), thus neglecting less frequent ones. In their paper, the agent's controller is selected using rank-based selection from the agent's list of chromosomes. The authors argue that when a specific task is to be addressed, a task-driven selection pressure is necessary. This idea is discussed in the remainder of this paper.

In the aforementioned works, authors used different classical selection operators from evolutionary computation in on-line distributed ER algorithms. It is however not clear if these operators perform in the same fashion as when they are used in an off-line non-distributed manner. In an on-line and distributed context, evolutionary dynamics are different, since selection is performed locally at the agent level and over the individuals whose vehicles had the opportunity to meet. In addition, and this is not inherent to on-line distributed evolution but to many ER contexts, fitness evaluation is intrinsically noisy as the agents evaluate their controllers in different conditions, which may have a great impact on their performance. A legitimate question one could ask is: does it still make sense to use selection?

In this paper, we compare different selection methods corresponding to different intensities of selection pressure in a task-driven context. We apply these methods in a modified version of mEDEA and measure their impact on two different swarm robotics tasks.

Algorithms

In this section, we describe the variant of mEDEA we used in our experiments (Algorithm 1). It is run by all the agents of the swarm independently in a distributed manner. At any time, each agent possesses a single controller which is randomly initialized at the beginning of evolution.

The main difference w.r.t. mEDEA is that the algorithm alternates between two phases, namely an evaluation phase, in which the agent runs, evaluates and transmits its controller to nearby listening agents, and a listening phase, in which the agent does not move and listens to incoming chromosomes, sent by nearby agents. The evaluation and the listening phases last $T_{\rm e}$ and $T_{\rm l}$ respectively, and, for different robots, they take place at different moments. Since the different robots are desynchronized, robots in the evaluation

phase are able to spread their genomes to other robots that are in the listening phase.

If only one common phase takes place, an agent that turns on the spot transmits its controller to any fitter agent crossing it, as broadcast and reception are simultaneous. This separation in two phases is inspired from MONEE where it is argued that it lessens the spread of poorly achieving controllers. Also, task-driven selection was introduced in MONEE to simultaneously tackle several tasks.

The agent's controller is executed and evaluated during the evaluation phase. For each agent, this phase lasts $T_{\rm e}$ time-steps at most 1. During this phase, at each time-step the agent executes its current controller by reading the sensors' inputs and computing the motors' outputs. The agent also updates the fitness value of the controller, based on the outcome of the its actions, and locally broadcasts both the chromosome corresponding to its controller and its current fitness value.

Once the $T_{\rm e}$ evaluation steps are elapsed, the agent begins its listening phase, which lasts T_1 time-steps. During this phase, the agent stops and listens for incoming chromosomes from nearby passing agents (agents that are in their evaluation phase). These chromosomes are transmitted along with their respective fitness values. Consequently, at the end of this phase, an agent has a local list of chromosomes and fitnesses, or local population. Another difference w.r.t mEDEA is that the local population also contains the agent's current chromosome. This is done to ensure that all agents always have at least one chromosome in their respective populations, which happens particularly when an agent is isolated during its listening phase and does not receive any other chromosome. In mEDEA, isolated agents stay inactive until they receive a chromosome from another agent passing by.

After the listening period, the agent needs to load a new controller for its next evaluation phase. To do so, it selects a chromosome from its list using one of the selection methods discussed further. The selected chromosome is then mutated and becomes the agent's active controller. In this case, mutation consists in adding a normal random variable with mean 0 and variance σ^2 to each gene (each synaptic weight of the neuro-controller).

Once the next controller is chosen, the list is emptied. This means selection is performed on a list of chromosomes that have been collected by the agent during the previous listening phase. At this time, the new controller's evaluation phase begins. We consider one iteration of the algorithm (evaluation plus listening phase) as one generation.

The selection method selects the new chromosome among the collected ones based on their fitness. This can be done in different manners, depending on the desired intensity of selection pressure. In this paper we compare four different

 $^{^{1}}$ A little random number is substracted from $T_{\rm e}$ so as the evaluation phases of the agents are not synchronized.

Algorithm 1 mEDEA

```
1: g_a := random()
 2: while true do
      1 := \emptyset
 4:
      // Evaluation phase
 5:
       for t=1 to T_{\rm e} do
 6:
         exec(g_a)
 7:
         broadcast(g_a)
 8:
       end for
 9:
       // Listening phase
10:
       for t = 1 to T_1 do
11:
         l := l \cup listen()
12:
       end for
13:
       1 := 1 \bigcup \{g_a\}
14:
       selected := select(1)
15:
       g_a := mutate(selected)
16: end while
```

selection methods, each one defining a different intensity of task-driven selection pressure. The choice of these selection methods aims at giving a large span of intensities of selection pressure, from the strongest (*Best*), to the lowest (*Random*):

Best Selection: This method deterministically selects the controller with the highest fitness. This is the selection method with the strongest selection pressure, as the agent will never be allowed to select a controller with a lower fitness than the previous one. *Best* selection can be compared to an elitist selection scheme where the best fit controllers are always kept.

Algorithm 2 Best selection

```
1: order x_i and index as x_{i:n} such that: f(x_{1:n}) \ge f(x_{2:n}) \ge \ldots \ge f(x_{n:n})
2: return x_{1:n}
```

Rank-Based Selection: In this case, selection probabilities are assigned to each controller according to their rank, *i.e.* the position of the controller in the list, once sorted w.r.t. fitness values. The best controller has the highest probability of being selected; however, less fit controllers still have a positive probability of being selected. Traditionally, this method is preferred to Roulette Wheel selection that assigns individuals probabilities proportional to their fitness values, which highly biases evolution toward best individuals.

Binary Tournament: This method uniformly samples a number of controllers equal to the size of the tournament (two in our case) and selects the one with the highest fitness. Here, the selection pressure is adjusted through the size of

Algorithm 3 Rank-based selection

```
1: order x_i and index as x_{i:n} such that: f(x_{1:n}) \geq f(x_{2:n}) \geq \ldots \geq f(x_{n:n})

2: select x_{i:n} with probability Pr(x_{i:n}) = \frac{n+1-i}{1+2+\ldots+n}

3: return x_{i:n}
```

the tournament: the higher the size, the higher the selection pressure, the extreme case being when the tournament size is equal to the size of the population. In this case, the best controller is chosen². Conversely, when the size of the tournament is two, the induced selection pressure is the lowest.

Algorithm 4 k-Tournament selection

```
1: uniformly sample k x_i, noted \{x_{1:k}, \ldots, x_{k:k}\}

2: order x_{i:k} such that: f(x_{1:k}) \geq f(x_{2:k}) \geq \ldots \geq f(x_{k:k})

3: return x_{1:k}
```

Random Selection: This method selects a controller in the local population at random, disregarding its fitness value and therefore inducing no task-driven selection pressure at all. *Randon* selection is considered as a baseline for comparisons with the other methods that effectively induce a certain task-driven selection pressure. As discussed in the previous section, this is the selection operator used by mEDEA for evolving survival capabilities of the swarm without any task-driven explicit goal. By considering *Random* in our experiments, we aim to compare the original mEDEA selection scheme with more selective operators.

Each one of these four selection methods induces a different intensity of selection pressure on the evolution of the swarm. In the next section, we describe our experiments comparing the impact of each one of these intensities.

Experiments

We compare these selection methods on a set of experiments in simulation for two different tasks, fast-forward navigation and collective foraging, which are two well-studied benchmarks in swarm robotics. All our experiments were performed on the RoboRobo simulator (Bredeche et al. (2013)).

Description

In all experiments, a swarm of robotic agents is deployed in a bounded environment containing static obstacles (black lines in Figure 1). Agents also perceive other agents as obstacles.

All the agents in the swarm are morphologically homogeneous, *i.e.* they have the same physical properties, sensors and motors, and only differ in the parameters of their respective controllers. Each agent has 8 obstacle proximity sensors

²It is assumed that sampling is performed without replacement.

evenly distributed around the agent, and 8 food item sensors are added in the case of the foraging task. An item sensor measures the distance to the closest item in the direction of the sensor. These simulated agents are similar to Khepera or e-puck robots.

We use a recurrent neural network as the architecture of the neuro-controllers of the agents (Figure 1). The inputs of the network are the activation values of all sensors and the 2 outputs correspond to the translational and rotational velocities of the agent. The activation function of the output neurons is a hyperbolic tangent, taking values in [-1, +1]. Two bias connections (one for each output neuron), as well as 4 recurrent connections (previous speed and previous rotation for both outputs) are added. This setup yields 22 connection weights for the navigation task and 38 for the foraging task in the neuro-controller. The chromosome of the controller is the vector of these weights. Table 1 summarizes the different parameters used in our experiments.

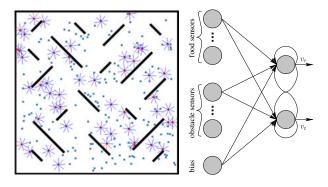

Figure 1: Left: the simulation environment containing agents (red dots with thin hairlines representing sensors), obstacles (dark lines) and food items (blue dots). Right: the architecture of the neuro-controller.

In the navigation task, agents must learn to move as fast and straight as possible in the environment while avoiding obstacles, whereas in the foraging task, agents must collect food items present in the environment (Figure 1). An item is collected when an agent passes over it, at which time it is replaced by another item at a random location.

We define the fitness function for the navigation task after the one introduced in (Nolfi and Floreano (2000)). Each agent r computes its fitness at generation g as:

$$f_r^g = \sum_{t=1}^{T_e} v_t(t) \cdot (1 - |v_r(t)|) \cdot min(a_s(t))$$
 (1)

where $v_t(t)$, $v_r(t)$ and $a_s(t)$ are respectively the translational velocity, the rotational velocity and the activations of the obstacle sensors of the agent at each time-step t of its evaluation phase.

In the foraging task, a controller's fitness is computed as the number of items collected during its evaluation phase.

	1 &									
Experiments										
Number of food items	150									
Swarm size	50 agents									
Exp. length	5×10^5 sim. steps									
Number of runs	30									
Evolution										
Evolution length	~ 250 generations									
T_e	2000 - rand(0, 500) sim. steps									
T_l	200 sim. steps									

Table 1: Experimental settings.

Furthermore, since we are interested in the performance of the entire swarm, we define the swarm fitness as the sum of the individual fitness of all agents at each generation:

$$F_s(g) = \sum_{r \in swarm} f_r^g \tag{2}$$

 $\sigma = 0.5$

Measures

Chromosome size

Mutation step-size

A characteristic of on-line ER is that agents learn as they are performing the actual task in an open-ended way. In this context, the best fitness ever reached by the swarm is not a reliable measure, since it only reflects a "good" performance at one point of the evolution. Furthermore, fitness evaluation is inherently noisy, due to different evaluation conditions encountered by the agents. Therefore, we introduce four measures that will be used to compare the impact of the different selection methods. These measures summarize information on the swarm spanning over several generations. They are used only for evaluation and comparison of the selection methods and are computed once the evolution has ended. A pictorial description of these four measures is shown in Figure 2.

- Average accumulated swarm fitness (f_c) : is the average swarm fitness in the last generations. This metric reflects the performance of the swarm at the end of the evolution. In our experiments, we compute the average over the last 8% generations.
- Fixed budget swarm fitness (f_b) : is the swarm fitness reached at a certain generation (computational budget). This measure helps to compare different methods on the same grounds. In our experiments, we measure this value at 92% of the evolution, which corresponds to the first generation considered in the computation of f_c .
- Time to reach target (g_f) : is the first generation at which a predefined target fitness is reached. If this level is never reached, g_f corresponds to the last generation. We fixed the target at 80% of the maximum fitness reached over

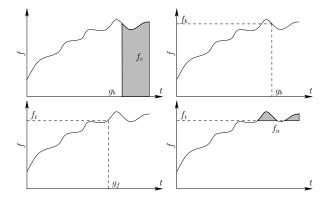

Figure 2: A pictorial description of the four comparison measures. From top to bottom and left to right: the average accumulated swarm fitness, the fixed budget swarm fitness, the time to reach target and the accumulated fitness above target.

all runs and all selection methods. This metric reflects a certain convergence rate of the algorithms, *i.e.* how fast the swarm hits the target fitness on the task at hand.

• Accumulated fitness above target (f_a) : is the sum of all swarm fitness values above a predefined target fitness. It reflects to which extent the target level is exceeded and if this performance is maintained over the long run. We used the same target fitness as with g_f .

These comparison measures are not to be taken individually. For instance f_c and f_b complement each other and give an indication of the level and stability of the performance reached by the swarm at the end of evolution. If f_b and f_c are close then performance of the swarm is stable. Also, g_f and f_a combined reflect how fast a given fitness level is reached and to which extent that level is exceeded. Adding the two latter measures to f_c shows if that trend is maintained.

Results and discussion

For both navigation and foraging tasks, we run 30 independent runs for each selection method, and we measured F_s at each generation in all runs. Figures 3 and 4 show the median F_s per generation over the 30 runs for each task. We computed the four performance metrics in the case of navigation (Figure 5) and of foraging (Figure 6). For both tasks, we performed pairwise³ Mann-Whitney tests at 99% confidence on these measures, between the four selection methods.

On the one hand, upon analysis of Figure 3 and Figure 4, we observe that the swarm rapidly reaches a high fitness level in both tasks whenever there is a task-driven selection pressure, *i.e.* with *Best, Rank-based* or *Binary tournament* selection. On the other hand, without any selection pressure

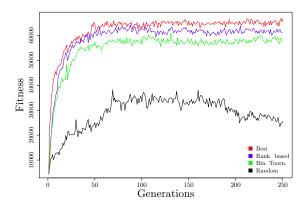

Figure 3: Median swarm fitness per generation over the 30 runs for the navigation task.

(*Random*), learning is much slower. Furthermore, for the three former selection methods the algorithm reaches comparable levels of performance in terms of median values of the swarm fitness. An exception can be noted for *Best* selection in the foraging task, which outperforms *Rank-based* and *Binary tournament*.

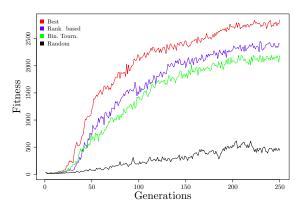

Figure 4: Median swarm fitness per generation over the 30 runs for the foraging task.

Despite the lower performances achieved by *Random*, the swarm still manages to learn behaviors for both tasks. This can be seen in the increasing trend of the median swarm fitness in Figure 3 and Figure 4. This result is expected on the navigation task. As it is the case in (Bredeche and Montanier (2010)), environmental pressure drives evolution toward behaviors that maximize mating opportunities and thus behaviors that explore the environment, increasing the swarm fitness.

The same trend is also observed on the foraging task. The improvement is slower but still present with *Random* selection. This could be explained by the fact that collecting

³Pairwise in this context means all combinations of pairs of selection methods, six combinations in our case.

items is a byproduct of maximizing mating opportunities. Agents collect items by chance while they navigate trying to mate. When inspecting the swarm in the simulator, we observed that, when selection pressure is present, the evolved behaviors drive the agents toward food items which means that the food sensors are in fact exploited. In other words, evolution drove the controllers to use these sensors. However, without any selection pressure (*Random*), there can not be a similar drive. We also observed this in the simulator: agents were not attracted by food items for *Random* selection.

When we analyze the comparison measures we introduced earlier, similar trends are observed. Figure 5 (respectively Figure 6) shows the box and whiskers plots of the four measures for each selection method over the 30 runs for the navigation task (respectively the foraging task).

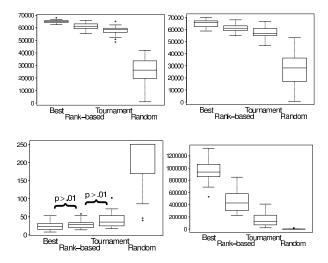

Figure 5: Box and whisker plots (30 independent runs) of the comparison measures for the four selection methods on the navigation task. From top to bottom and left to right: f_c , f_b , g_f and f_a . The label p>0.01 indicates no statistical difference for the corresponding two selection methods.

On the navigation task, the pairwise comparisons of the four measures, using Mann-Whitney tests at 99% confidence level, yield significant statistical difference between all selection methods except between *Best* and *Rank-based* (p-value=0.0795) and between *Rank-based* and *Binary tournament* (p-value 0.0116) in the case of the time to reach target (g_f) .

We also observe that Best reaches a higher swarm fitness for the fixed budget than the rest of selection methods, and this level is maintained at the end of evolution, as is shown in f_c and f_b (upper left and right in the figure). The target fitness level is rapidly reached for the three methods inducing selection pressure, and there is not significant difference between Best and Rank-based, nor between Rank-based and

Binary Tournament w.r.t g_f (lower left). Furthermore, in the case of Best, the required level is not only reached but surpassed during the entire evolution, leading to a value of f_a much higher than the ones of the rest of selection methods (lower right). However, this is not the case for Random selection that has much lower f_b (upper right) and f_c (upper left), and does not reach the target fitness level on more than half the runs that were launched (lower left and right).

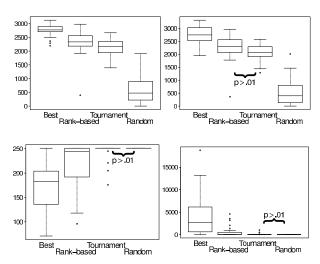

Figure 6: Box and whisker plots (30 independent runs) of the comparison measures for the four selection methods on the foraging task. From top to bottom and left to right: f_c , f_b , g_f and f_a . The label p>0.01 indicates no statistical difference for the corresponding two selection methods.

On the foraging task, there is a significant difference for all pairwise comparisons, except between Binary Tournament and Random in the case of the time to reach target, g_f , and the accumulated fitness above target, f_a , (p-value=0.0419 in both cases). This is explained by the fact that very few runs attained the target fitness⁴ in which case g_f is the last generation and f_a is almost zero. There is also no statistical difference between Rank-based and Binary Tournament on the fixed budget swarm fitness, f_b , (p-value=0.0105). This means that Binary Tournament reaches a fitness at the given budget that is comparable to the one of Rank-based, but it does not maintain this level, since for these two methods the difference is significant on f_c .

Best also gives better results on the foraging task: a high swarm fitness is reached and maintained at the end of evolution (f_b and f_c , upper left and right). It surpasses the target fitness level in almost all runs much faster and to a larger extent than Rank-based, that also manages to reach the required level for most runs (g_f , lower left), although by a

 $^{^4}$ For both tasks, the target fitness is 80% of the highest fitness reached by all methods during all runs.

lower level (f_a , lower right). This is not the case for *Tournament* and *Random* that do not achieve the target fitness level for most runs (lower left and right).

We can observe that all task-driven selection pressures yield much better performances on both tasks compared to *Random* selection. Consequently, we may conclude that selection pressure has a positive impact on performances, when solving a given task, and when the objective is not only to achieve adaptation of the swarm as it was the original motivation of mEDEA. Further, statistical tests show a direct correlation between the selection pressure and the performances achieved by the swarm on the two considered tasks. In other words, the stronger the selection pressure, the better the performances reached by the swarm.

In general, it has been argued that elitist strategies are not desirable in traditional EA's, and the same argument holds for traditional ER. This is due to the fact that elitist strategies may lead to a premature convergence at local optima. There exists an extensive body of work, especially in non-convex optimization, where it is preferable to explicitly maintain a certain level of diversity in the population to escape local optima and to deal with the exploration vs. exploitation dilemma. This requirement is perhaps not as strong in the context of distributed ER as our experiments show. Selection is performed among a portion of the population at the agent level, therefore, one might argue that these algorithms already maintain a certain level of diversity inherent to the fact that sub-populations are distributed on the different agents. Comparisons with other approaches in which separated sub-populations are evolved, such as spatially structured EA's (Tomassini (2005)) and island models (Alba and Tomassini (2002)), could give further insights on the dynamics of this kind of evolution.

Conclusions

In this paper, we studied the impact of task-driven selection pressures in on-line distributed ER for swarm behavior learning. This kind of algorithms raises several questions concerning the usefulness of selection pressure (partial views of population, noisy fitness values, etc.). We compared four selection methods inducing different intensities of selection pressure on two tasks: navigation with obstacle avoidance and collective foraging. Our experiments show that selection pressure largely improves performances, and that the intensity of the selection operator positively correlates with the performances of the swarm.

Foraging and navigation can be considered as relatively simple tasks and we believe that more complex and challenging ones, involving deceptive fitness functions, could give further insights on selection and evolution dynamics in the distributed case.

Acknowledgements

The authors would like to thank Evert Haasdijk for providing the version of RoboRobo simulator we used in the experiments, and for his insightful comments.

The Relay Chain: A Scalable Dynamic Communication link between an Exploratory Underwater Shoal and a Surface Vehicle

Becky Naylor¹, Mark Read², Jon Timmis¹ and Andy Tyrrell¹

¹ Department of Electronics, University of York

Abstract

In this paper we present the Relay Chain: a new algorithm central to a novel strategy for exploring underwater environments using a swarm of autonomous underwater vehicles (AUVs). The Relay Chain provides a mobile, scalable and dynamic communication link between the water's surface and a shoal of AUVs exploring the sea bed. The chain tracks the shoal as it explores, recruiting and returning AUVs from and to the shoal to modulate the length of the chain as required. The chain can instruct the shoal to reverse course when it travels too far from the starting point and there are no further AUVs to recruit. Given the challenging underwater environment, chain breakages are however inevitable, and as such we consider a number of recovery strategies to address chain breakages and minimise the time for which messages destined to the surface from the shoal are delayed. A simple 'turn and search' strategy is contrasted with strategies that depend on absolute positioning systems of varying accuracy. Implementing underwater absolute positioning systems is challenging, and our results highlight how accurate such a system must be to outperform more naive strategies, and hence be considered a worthwhile investment. We find the accuracy must be within 20cm, being 40% of AUV sensor range.

Introduction

Underwater exploration is a challenging task, the environment is noisy and difficult to access and navigate, and communication signals are short range due to heavy attenuation. The challenge can be met through a swarm of small autonomous underwater vehicles (AUVs) which divide aspects of the task between them and as a collective provide robustness in the difficult environment. The CoCoRo project is developing such a swarm of AUVs to address complex problems in a decentralised manner, sharing information only locally between robots (Schmickl T.et al. (2011)).

CoCoRo's underwater exploration strategy comprises two swarms: an *exploratory shoal* of AUVs that navigate the sea bed, and a *Relay Chain* of AUVs capable of relaying messages to one another, thus maintaining a communication link between the shoal and water's surface. We focus in this paper on the Relay Chain algorithm. The Relay Chain is a highly dynamic swarm: each link in the chain independently

coordinates its movement such that the chain tracks the shoal as it explores. The chain can recruit and return AUVs from and to the shoal into the chain to ensure it does not break when the shoal travels further way, and does not needlessly occupy AUVs when it returns. When there are no further AUVs that can be recruited, the chain can instruct the shoal to reverse course, further ensuring the chain does not break.

This paper presents the core Relay Chain algorithm, and an investigation into alternative strategies to deal with breakages in the chain when they occur. Despite the Relay Chain's dynamic and robust design, performing 3D collective coordination in noisy underwater environments using robots with limited sensor and communication ranges will certainly lead to AUVs in the chain losing contact with one another. We evaluate both a relatively naive recovery strategy whereby AUVs having lost contact with neighbouring links in the chain simply turn around and search for them, and a strategy based on AUVs localising one another through an absolute positioning system. Implementing an underwater absolute positioning system is highly challenging, and our analysis considers systems of varying accuracy, thereby highlighting how accurate such a positioning system must be to outperform the more simple strategy. The evaluation is based on the time required to send a message from the shoal to the water's surface, given that it may be delayed in an AUV that has temporarily lost contact with the next link in the chain. Recovery strategies must minimise the time for which the chain is broken, allowing the shoal to quickly report findings to the water's surface.

Both the Relay Chain algorithm design and the experiments reported here are performed in the CoCoRoSim simulation, which has been developed alongside, and calibrated to, the real-world CoCoRo AUV hardware in anticipation of its completion (Read M. *et al.* (2013)). Simulation represents a powerful tool for algorithmic development and evaluation, as sophisticated performance metrics can be applied with ease, and development can focus purely on algorithmic concerns free of hardware faults, and without the added time required to reprogram, deploy and collect AUVs. It has previously been employed in developing the exploratory shoal

² Charles Perkins Centre, The University of Sydney

algorithm used here (Read M. et al. (2013)).

Our manuscript is organised as follows. First we consider the CoCoRo AUV configurations and capabilities, and the simulation environment. We summarise the previously published shoaling algorithm, used here by the exploratory shoal, before describing the Relay Chain algorithm itself. Thereafter we report our hypothesis-driven experiments to evaluate potential chain-breakage recovery strategies, and then conclude the paper.

AUV Configuration and Simulation

The CoCoRoSim Netlogo3D simulation reflects the design of the bespoke AUV hardware developed for CoCoRo (these AUVs are named "Jeff"), and has been calibrated to provide representative behaviour of the real AUVs. The Jeff platform is 25 x 12 x 5cm in dimension, uses thrusters to propel itself forwards or backwards and control its yaw, and can adjust its depth through a buoyancy pump. Omnidirectional communication with a range of 50cm is provided by a radio-frequency (RF) modulator. Six bluelight sensor systems, comprising LEDs and photodiodes, located on the front, back, left, right, top and bottom of the AUV provide detection of obstacles and other AUVs. Each sensor system can perceive the distance to obstacles within an angle of 120 degrees and a range of 50cm; exact triangulation within this cone is not possible, only distance can be discerned (Scuola Superiore Sant'Anna and CoCoRo partners (2012); Universit libre de Bruxelles and CoCoRo partners (2013)).

The CoCoRoSim Netlogo3D simulation reflects sensor and actuator capabilities of Jeff, and its physics engine has been calibrated against empirical data generated from the previous CoCoRo AUV design (Read M. et al. (2013)). The water in the simulator causes drag for translational and rotational movement. The robot arena (Figure 5) is a rectangular tank with a fixed 'water level' as the top surface, the walls and floor of the tank are represented as solid surfaces which are detectable by the bluelight sensors.

Exploratory Shoal

The exploratory shoal uses an algorithm based on Reynolds' boids (Reynolds, 1987), the implementation of which is described in Read M. et al. (2013); only a brief summary is provided here. An AUV's movement is dictated by the weighted sum of three desired trajectories, calculated based on rules for cohesion, alignment and separation. Separation provides a trajectory away from other AUVs found within a threshold distance, and is designed to prevent collisions. The cohesion trajectory points towards other AUVs within detection range, and prevents AUVs losing contact with one another. The alignment trajectory reflects the average orientation of neighbouring AUVs, and seeks to align AUV orientations. The trajectories for each rule are calculated at regular time intervals, and their weighted sum governs AUV thruster and buoyancy pump actuation.

Separation and cohesion rules are informed by distance data provided by the bluelight sensors, with distance measures beyond 95% of the maximum sensor range excluded to ignore sensor noise. The separation threshold is 30% of sensor maximum range. The alignment rule uses data obtained from AUVs sharing their heading information with one another over RF.

Relay Chain Algorithm

The Relay Chain algorithm controls the initial formation and the maintenance of a communication link between the exploratory shoal and the surface.

Formation

A group of AUVs is deployed on the water surface, some of these will form the Relay Chain and the rest will join the exploratory shoal. The process is shown in Figure 1. All of the AUVs begin the process in the *explore* state (Figure 1). One AUV is chosen to be the 'seed' to start the formation. This becomes the start chain AUV (Figure 1). The start AUV remains stationary in the centre at the surface of the water. It is representative of any surface vehicle such as a fixed base station or a boat. The algorithm can also work with a mobile surface vehicle, with the chain following the vehicle in the same manner as the exploratory shoal, but for simplicity it remains stationary in the present experiments. This start AUV requests a number of vehicles to go to specific depths, each represents one layer of the chain. These will be the middle chain AUVs and the last one the end chain AUV (Figure 1).

For example in a water depth of 1m, five AUVs are recruited by the seed to initialise the chain. The remaining vehicles follow the chain downwards and form the exploratory shoal. The AUVs head to a target depth calculated using a user defined distance between AUVs. Once in position each AUV in the chain communicates with the AUVs either side of it, to keep at a depth halfway between the two of them. Each AUV in the chain knows the ID number of the 'next' and 'previous' AUVs in the chain, this is labelled from top to bottom so next is the one below and previous is the one above it. So that the algorithm remains decentralised each AUV is only aware of its local position and does not know globally where it is within the chain. An image of chain and shoal after initialisation is shown in Figure 2, chain AUVs are black and shoal AUVs are white.

Chain States

The Relay Chain algorithm splits the AUVs into task driven subgroups of: the exploratory shoal, the Relay Chain and navigation. These are the highest level states *explore*, *chain* and *navigate* in the state diagram (Figure 1).

Chain AUVs maintain a *position* state, to identify whether they are the *start* AUV at the top of the chain, a *middle* AUV or the *end* AUV at the bottom of the chain. The start and

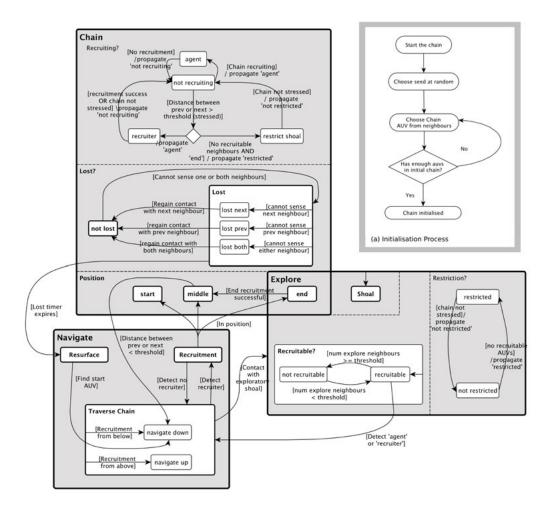

Figure 1: Complete state diagram illustrating the operation of the Relay Chain algorithm. The three core states are *chain* AUVs in the Relay Chain, *explore* AUVs in the exploratory shoal and *navigate* AUVs moving between *chain* and *explore*. The initialisation flow chart is shown in (a)

end AUVs are special cases. As discussed in the initialising section the start AUV remains at the water's surface and initialises chain formation. The *end* AUV is both a member of the chain and the exploratory shoal (see Figure 1). This means that it follows the shoal as it explores the environment and provides a link to the rest of the chain.

To maintain contact with the exploratory shoal the chain can dynamically change length by recruiting more AUVs or having AUVs leave the chain. The chain must add more AUVs to extend if the shoal moves away from the start AUV, so the chain has 'too few' members. It can also gain 'too many' members, for example if the shoal changes direction and returns towards the chain. Whether the chain has 'too many' or 'too few' AUVs is determined by thresholding the distance between chain AUVs.

To determine their desired position all *middle chain* AUVs monitor the distance and heading to the AUVs on either side

of them in the chain. They aim to stay in a position halfway between the AUVs on either side of them. If the halfway distance exceeds a 'stress threshold' then it will stay nearer the 'previous' neighbour (one above in the chain). This is so that the 'stress' is transferred down the chain, nearer to the exploratory shoal; making it easier for AUVs to be recruited directly into the chain.

When the distance between the shoal and *end* chain AUV reaches a threshold the *end* AUV in the chain switches to the *recruiter* state (in the *Recruiting?* section in *chain* Figure 1). It propagates a message through the other chain AUVs to become *agents* to direct any *recruitable* AUVs to the site of the *recruiter*. The *recruitable* AUV will enter either *navigate up* or *navigate down* state depending on the direction it is given by the 'agent'.

A *recruitable* AUV is typically one from the exploratory shoal (*explore* state in Figure 1), but an AUV that is already

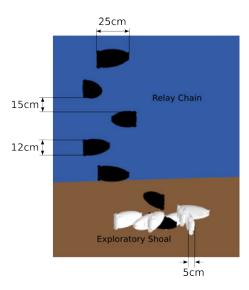

Figure 2: CoCoRo simulation environment, Relay Chain robots are black and exploratory shoal are white.

traversing the chain can also be recruited. If a recruitable AUV senses a recruiter or agent it enters the traverse chain state. Once it finds a recruiter the AUV will enter the recruitment state and manoeuvre into position to join the chain (as shown in the navigate state in Figure 1). All available AUVs will respond to a recruiter, but once the first responder is in position it joins the chain and the recruitment process stops (unless more AUVs are required). When a recruitment AUV can no longer see a recruiter it returns to the traverse chain state. When a traverse chain AUV cannot see a recruiter or agent and has contact with the exploratory shoal then it returns to the explore state. Once recruited, the new AUV will become the end AUV and the original end AUV will change state to become a middle AUV. (Position section in chain state Figure 1.

Once *recruitment* is successful, or if the distance between the end AUV and its previous neighbour has reduced below the 'stress threshold' by movement of the shoal, the *end* chain AUV switches to *not recruiting*. It will then propagate this message to the other chain AUVs to switch to the *not recruiting* state from the *agent* state (as seen in the *recruiting*? section in *chain* Figure 1).

If there are insufficient *recruitable* AUVs within range of the *end* chain AUV then the *end* AUV will pass a *restrict* message to the shoal. The number of *recruitable* AUVs required in the shoal is determined by a user specified threshold, its setting depends on the number of AUVs being used. Here for example with 15 AUVs in the simulation the 'recuritable threshold' is 2. The *end* AUV transmits a message to the shoal AUVs in range to enter the *restricted* state. They propagate this to other shoal members, outside of the range of the *end* chain AUV (in *restriction?* section in the *explore* state in Figure 1). The entire shoal is either *restricted* or

not restricted, though individual AUVs may have opposing states while the message propagates through the shoal. Once in the restricted state the exploratory shoal AUVs will turn around (180 degrees) and head back towards the chain. This reduces the distance between the chain members and minimises the risk of the chain breaking.

To identify whether there are unnecessary AUVs in the chain each of the *middle* position chain AUVs compares the distance between themself and the AUVs either side of them in the chain to a 'slackness threshold'. Both this and the 'stress threshold' are a proportion of the bluelight range of the AUVs. If an AUV is too close to its neighbour, according to the threshold, the AUV will send an RF message to the next and previous AUVs in the chain announcing that it is leaving. The next and previous IDs of both neighbour AUVs are updated to remove the AUV from the chain. It will then enter the *traverse chain navigate* state and *navigate down* to the exploratory shoal as shown in Figure 1. Once it has contact with the exploratory shoal it changes to the *explore* state to join the shoal. The *traverse chain* AUVs move alongside the chain, as shown in Figure 3.

As shown in Figure 1, all *chain* AUVs have a *lost* status. A *chain* AUV is considered *lost* if it loses bluelight contact with either of its neighbours. This is further split to identify on which side the AUV has lost contact with. If an AUV remains *lost* for a given duration (e.g. 1 minute) then it is told to *resurface*. AUVs in the *resurface* state head to the surface at the coordinates they are currently at. They then use GPS to find the *start* AUV at the surface of the water, then enter the *traverse chain* state to rejoin the exploratory shoal or be recruited into the chain.

All of the AUVs utilise shoaling behaviours as described in the Exploratory Shoal section. The parameters are set differently depending on the desired behaviour, by weighting each of the rules' importance. For example; in the unrestricted *explore* state AUVs have a balance between cohesion, alignment and separation to produce shoaling behaviour. When in the *traverse chain* state the separation rule is most important, so that the AUV keeps moving rather than being attracted to a chain AUV and staying on one of the layers. The cohesion has a weight half that of the separation, so that the AUV follows the chain and does not head off in some other direction. The alignment rule is given a weight of 0, because the AUV is not in a shoal to align with.

Recovering lost AUVs

Knowledge of position is important for the Relay Chain algorithm, because the AUVs aim to maintain a position based on their neighbours. Using only the onboard sensors it is possible to work out the necessary heading locally. An AUV triangulates where the neighbour is by detecting which of its bluelight sensors can sense the neighbour. A problem arises when an AUV moves out of bluelight range of one or both of its neighbours. It no longer has any positional information

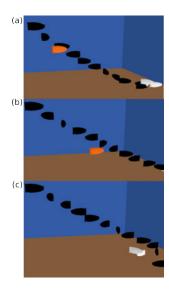

Figure 3: An AUV traversing down the chain to the exploratory shoal, the traversing AUV is shown in orange. Stage (a) shows it leaving the chain after the distance between it and its neighbours reduced below a threshold. Stage (b) shows the progress down the chain and stage (c) shows it joining the exploratory shoal.

about the neighbour(s). Such an AUV is considered 'lost' and each AUV has a lost status to store which neighbours (above or below) it has lost.

If one or more AUVs are lost, communications can no longer be passed along the chain. To solve the problem of finding the chain when lost, two alternative strategies are proposed and compared.

The first strategy is called 'Turn and Search', it is the simpler of the two strategies and can be performed without any additional hardware. In Turn and Search, when an AUV becomes lost it turns around by 180 degrees with a random offset of \pm 5 degrees (chosen using a uniform distribution). A 100s timer is started, again with an added uniformly chosen random component of up to 150s. If the timer expires and the AUV has not refound the chain then it turns again. This process continues until the chain is found. An example path is shown by the trace in Figure 4. The AUVs still use their shoaling parameters and avoid collisions.

In Turn and Search recovery, if the AUV remains lost for over a threshold time of 400s then it resurfaces to find the chain from the top. The threshold can be adjusted depending on the desired task and importance of refinding the chain.

The second strategy is Absolute Positioning (AP). While this may generally seem a more suitable positioning solution than the use of bluelight triangulation, the accuracy of such systems is limited. As the AUVs being used are small the accuracy of the position is important. This strategy requires additional hardware, so is only desirable if Turn

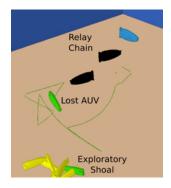

Figure 4: Example path taken by a lost AUV using Turn and Search recovery. The green AUV (fourth from the top) is lost and the trail is the path it has taken.

and Search is ineffective.

Positioning underwater cannot be achieved with GPS but there are different solutions including hydro-acoustic, image based and inertial systems. Of these, acoustic systems are most applicable to CoCoRo AUVs and tank based test scenarios. Image based systems use differences in the environment surrounding the AUVs, for example the seabed (Garcia et al. (2001)). This is not well suited to the tank environment used for testing the CoCoRo AUVs. Inertial systems are unlikely to offer any advantage over the existing system. They use measurements from gyroscopes and accelerometers on the AUV, so errors accumulate (Garcia et al. (2004)).

Acoustic systems use a set of beacons with fixed positions around the area in which the AUVs operate. The AUVs communicate acoustically with these beacons and the time for the signal to arrive is used to calculate the position (Alcocer et al. (2006)). The beacons can be attached to buoys with GPS receivers, so that they know their absolute position.

To provide specifications for a recovery system we compare the success of each method. We test three hypotheses:

- 'Using AP rather than Turn and Search recovery will reduce the mean time to wait before a message can be sent along the chain.'
- 2. 'The higher the accuracy of the AP the lower the average time to wait before a message can be sent along the chain'.
- 3. 'As the accuracy of the AP is reduced there will be a point when using AP only when an AUV is lost outperforms using AP all of the time'

To test these hypotheses we run two experiments. In the first Absolute Positioning (AP) is used to control the AUVs all of the time and in the second a combined bluelight triangulation and AP method. In experiment 2 the AP is only used when the AUV is lost.

In both experiments the results are compared to bluelight triangulation with Turn and Search recovery and to a control using 'random' movement.

Method

The simulator maintains absolute position information for each AUV, so when lost the AUVs can head back directly to their neighbour. In reality underwater systems will not have this type of sub-centimetre accuracy. To achieve this discrepancy in accuracy an offset is added to the absolute position value of both the lost AUV and the neighbour that it is heading back towards. This offset is randomly chosen from the specified range to each of the x, y and z coordinates. The value is chosen with uniform probability because this is the worst case scenario. This means that the AUV knows the position of its lost neighbour (or neighbours) within a cube centred on its real position. A different offset is used for the AUV's own value and each of its neighbours' values. Each time the AUV becomes lost a different offset is generated. As the AUVs have a depth sensor accurate to 0.1mm no offset is added to the lost AUV's own depth coordinate.

The experiment is run in a tank with a width and depth of 5m and a water level of 1m. All AUVs begin at the water level, in the centre of the tank with randomised starting headings. There are 15 AUVs, of which 5 (including the seed) are set to specific depths as described in the initialisation section.

The seed is fixed in the centre of the tank at the water surface. The 4 other chain AUVs are initialised to depths 15cm apart. The rest of the AUVs enter the 'explore' state and head down the chain. They are either recruited or form the exploratory shoal. At least 2 of the AUVs must be in the *explore* state. This provides enough length in the chain to extend to each corner of the tank when exploring. An example of this can be seen in Figure 5.

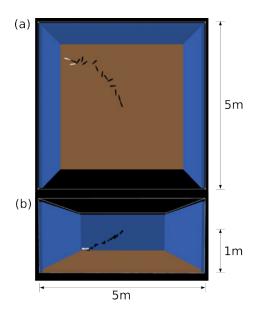

Figure 5: The Relay Chain in the tank used for experiments (a) top down view (b) front view.

In experiment 1 'partial AP' the AUVs will use bluelight triangulation when they are in range and AP when they are lost. For experiment 2 'full AP' the AUVs will always use AP to hold their position in the chain. Although they do not use bluelight triangulation the AUVs can still be 'lost' because once out of bluelight range they are out of communication range.

The simulation is run for 1 hour in simulation time. 1hr is sufficiently long for the shoal to explore the bottom of the tank. The simulation is repeated 500 times for each of the different AP accuracies. Offsets of between 0cm and 50cm are tested, 50cm represents a substantial offset as the AUVs are only 25cm by 12cm by 5cm. The range of accuracies is compared to the system without any absolute positioning, using the Turn and Search recovery method and also to a control version with 'random walk' movement with all AUVs in the Turn and Search recovery state at all times. The AUVs are given an initialisation period of 1 minute to allow them to reach their desired depths, then enter the recovery state for the remainder of the simulation run.

The success of the system is measured using the average time that it takes to send a message from one end of the chain to the other. This is important because the chain is necessary to convey messages, if the message takes too long then the information contained may no longer be valid.

The time between sending and receiving comprises two parts; firstly the time to physically transmit the data along the chain and secondly the time to wait until there are no lost AUVs so all AUVs can communicate with their neighbours.

The time to send the message itself is small compared to the potential time to wait until there are no lost AUVs. A typical message is 50 bytes and the AUVs can transmit at 28.8Kb/s. Each transfer will take 0.0139s and the chain can need no more than 13 transfers from one end to the other. Assuming negligible processing time the entire process will take at most 0.181s. The likelihood of the chain breaking while a message is physically being propagated is small, and the message can be resent if this occurs. The 'time to wait' component is therefore the critical factor, rather than the 'transmit time'.

The waiting time is determined by the contiguous time that the chain is broken for. For example if the chain is broken for a total duration of 60s then it is much preferable to have six 10s blocks than one 60s block. The chain is able to send a message in the gaps between the 10s blocks, rather than waiting the entire 60s before sending a message.

Results

The results using full AP are shown in Figure 6. In the graph 0 (no offset) is most accurate, each subsequent value is the offset in cm. The first column shows the control of 'random' movement when all AUVs are in Turn and Search recovery. The second column shows the system with no positional information other than the local bluelight triangulation.

The A test (Vargha A. *et al.* (2000)) is a non-parametric effect magnitude test which allows the comparison of the distribution of results for a comparison parameter with the distributions using alternative values. The A test indicates the probability that a randomly chosen sample from one distribution is larger than a randomly chosen sample from the other. A value of between 0 and 1 is returned by the test, with values higher than 0.71 or lower than 0.29 indicating 'large' differences between distributions. Large differences are assumed to be significant (Vargha A. *et al.* (2000)).

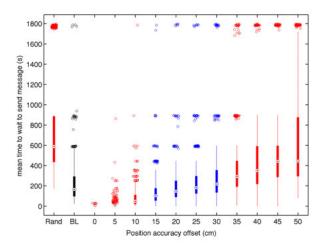

Figure 6: Mean time to wait before a message can be sent using full AP. Rand is random movement, BL is bluelight with Turn and Search (this is the A test comparison distribution) and numerical values are the AP offset.

The A test responses using different comparison values are provided in table 1. They show whether the difference between each column is significant. The colour of the column in Figure 6 represents the A test score of each distribution with a comparison to bluelight with Turn and Search (black in the graph). 'Red' columns are significantly different to the comparison distribution, 'blue' columns are not (values for each column are given in table 1).

From these the Turn and Search recovery method is significantly better than the random control. AP is significantly better than Turn and Search with an offset of up to 10cm, but significantly worse with an offset of 35cm or greater. An offset of 40cm or greater is not significantly different to the random control. When considering how much offset it takes before the system does not perform as well, 5cm is not significantly different to having no offset.

The results for partial AP (experiment 2) are shown in Figure 7. The A test responses are shown in table 1. For the partial AP, unlike full AP, all offsets are significantly better than the random control. Comparing the BL column with the AP columns shows that the AP values between 0 and 20 are

significantly better than the bluelight with Turn and Search. For partial AP offsets of 5 and 10cm are not significantly different to having no offset.

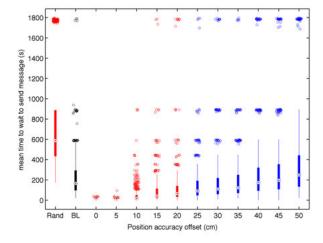

Figure 7: Mean time to wait before a message can be sent using partial AP. Rand is random movement, BL is bluelight with Turn and Search (this is the A test comparison distribution) and numerical values are the AP offset.

Discussion

The results presented above provide responses to the three hypotheses presented earlier. *Hypothesis 1 'Using AP rather than Turn and Search recovery will reduce the mean time to wait before a message can be sent along the chain.'* is shown to be true for both full and partial AP when the offset is 10cm or lower. The median average time to send a message (of the 500 runs) is 17.8s for full AP with 0 offset and 17.2s with partial AP compared to 166.4s with Turn and Search.

With too high an offset AP performs no better (or in the full AP experiment worse) than Turn and Search. This means for the hypothesis to be correct, the chosen AP system must be able to deliver accuracy to within 10cm for full AP and 20cm for partial AP.

Hypothesis 2 'The higher the accuracy of the AP the lower the average time to wait before a message can be sent along the chain' is also shown to be correct. It is true for both full and partial AP. There is a marked reduction in performance as the accuracy is decreased.

The system can function without significant degradation in the time to send a message, with an offset of 10cm when compared to a 0cm offset. When compared with a bluelight only system, an offset of up to 20cm is shown to be preferable. From this we can specify a system with an accuracy of 20cm or better be used.

Hypothesis 3 is 'As the accuracy of the AP is reduced there will be a point when using AP only when an AUV is

lost outperforms using AP all of the time'. Comparing the partial and full AP results shows that for values of 0, 5 and 10 there is no significant difference. For values of 15 and above the partial system is significantly better than the full system. An offset value of 15cm represents the switching point in performance. This result can be explained because with full AP the positioning is always altered by the offset. In partial AP the AUVs are able to use their bluelight sensors to triangulate their relative position, so are not affected by the offset at this time.

The clusters in Figures 6 and 7 can be explained by AUVs getting lost and not finding the chain again. The highest valued cluster is at the duration of the run.

In summary, for AP to be worthwhile for recovery of lost AUVs to the Relay Chain it must be accurate to within 20cm otherwise bluelight triangulation is preferable.

Conclusion

The Relay Chain has been shown to be a decentralised method of providing a link between AUVs exploring the environment and the surface of the water. It is scalable, resizing as the shoal moves around the environment.

Restriction of the shoal's movement if there are not enough recruitable AUVs prevents the Relay Chain breaking and keeps the shoal in communication range of the surface vehicle. Messages can be propagated in either direction along the chain, relaying exploration data from shoal to surface or instructions to the shoal.

A disadvantage of the Relay Chain is that the number of AUVs used restricts the number available in the shoal. This is a result of limited communication range underwater.

Extensions where the chain is likely to be successful include fault tolerance, because the decentralised nature of the algorithm means an AUV can be removed and the chain reposition and continue operating. The introduction of a more challenging environment with low visibility water should be handled by the same recovery mechanisms used for lost AUVs in clear water.

The challenges of underwater communication and positioning mean that the CoCoRo Jeff AUVs can lose sight of their neighbours in the chain. Once lost, using only the available sensors it is difficult to refind the chain. Two alternative recovery strategies are used to overcome this. Either method

provides some robustness to lost AUVs, though Absolute Positioning gives the best performance and is preferable to bluelight when the accuracy is within 20cm.

Collective Behaviors

Scale-free correlations in collective motion with position-based interactions

Extended Abstract

Introduction Collective Motion (CM) is observed in a variety of animal groups such as bird flocks and fish schools. In a recent study, Cavagna et al. (2010) found that the correlation lengths of speed and velocity fluctuations in starling flocks are not set by a specific interaction range, but are instead scale-free, proportional to the group size. So far, this observation has been justified by hypothesizing that flocks evolved to follow critical dynamics near a phase transition. where scale-free correlations are known to emerge. Criticality could provide an evolutionary advantage by allowing the flock to optimally respond to an external perturbation such as a predator attack. However, a criticality-based explanation may only be required in cases where interactions are based exclusively on relative orientations, as often assumed in CM models, following the seminal work by Vicsek et al. (1995). In this paper, we show that an alternative, more parsimonious, mechanism can produce scale-free correlations when considering interactions based on relative positions.

AE simulations We consider an active elasticity (AE) model (Ferrante et al., 2013), where N self-propelled agents are moving in 2D, with neighbors permanently linked by spring-like linear forces. Given the position \vec{x}_i and orientation θ_i of each agent i, the AE model is defined as:

$$\dot{\vec{x}}_i = v_0 \, \hat{n}_i + \alpha \, \left(\vec{F}_i \cdot \hat{n}_i \right) \, \hat{n}_i, \tag{1}$$

$$\dot{\theta}_i = \beta \left(\vec{F}_i \cdot \hat{n}_i^{\perp} \right) + D_{\theta} \, \xi_{\theta}.$$
 (2)

Here, v_0 is the preferred self-propulsion speed, α and β are the speed and angular force coupling coefficients, and \hat{n}_i and \hat{n}_i^{\perp} are unit vectors pointing parallel and perpendicular to the heading of agent i, respectively. The sum of elastic forces over agent i is given by: $\vec{F}_i = \sum_{j \in S_i} \left(-k/l_{ij}\right) \left(\|\vec{r}_{ij}\| - l_{ij}\right) \left(\vec{r}_{ij}/\|\vec{r}_{ij}\|\right)$, where S_i is the set of all j neighbors linked to agent i, the spring constants k/l_{ij} and natural lengths l_{ij} characterize the interactions between them, and $\vec{r}_{ij} = \vec{x}_j - \vec{x}_i$ are their relative positions. Noise is introduced by adding $D_{\theta} \, \xi_{\theta}$ in Eq. (2), where D_{θ} is the noise strength and ξ_{θ} a random variable with standard, zero-centered normal distribution of variance 1.

Simulations were carried out by integrating Eqs. (1) and (2) numerically. They were set up as a minimal AE-based version of the starling experiments by Cavagna et al. (2010). Parameters $l_{ij}=1$, $v_0=10$, k=100, $\alpha=2$, and $\beta=3$ were chosen to roughly mimic the experimental dynamics. The noise level was set to be high $(D_{\theta} = 0.628)$ but far from any critical point (here at $D_{\theta}^* \approx 1.1$, where the system transitions to a disordered, non-flocking state). We focus on the correlations that develop as the group turns due to strong local perturbations. This is continuously occurring in natural flocks as individuals at the edge of the group change their heading directions based on external stimuli. We mimic such situation by initializing all agents with $\theta = 0$, except for one (the *informed* agent), which is forced to head towards $\theta =$ $\pi/3$ during the whole run, while its speed is determined by Eq. (1). This corresponds roughly the natural flock turning dynamics described in (Attanasi et al., 2013).

Figure 1 displays snapshots of the AE simulations. At t=0.5 (a), the top-right corner of the hexagon is turning towards $\theta=\pi/3$, as imposed by the informed agent, while the rest continues heading to the right, still unperturbed. In the subsequent t=1.0 (b), 1.5 (d), and 2.0 (e) snapshots, the whole group starts to acquire the $\pi/3$ orientation, as the local perturbation spreads out through the system. Despite the turning and imposed noise, the degree of agent alignment remains high, with polarization order parameter $\psi=\|\sum_{i=1}^N \vec{v}_i\|/(Nv_0)$ ranging between 0.90 and 0.96 ($\psi=1$ indicates full alignment), which is consistent with the starling experiments. All panels display the informed agent detached from the hexagon, above and to the left of its top-right corner, since its virtual springs sustain large forces as they induce group turning, and are therefore very stretched.

Correlation function analysis We focus on the speed fluctuations $s_j = \|\vec{v}_j\| - \frac{1}{N} \sum_{i=1}^N \|\vec{v}_i\|$ and velocity fluctuations $\vec{u}_j = \vec{v}_j - \frac{1}{N} \sum_{i=1}^N \vec{v}_i$. As in (Cavagna et al., 2010), we compute the correlation function for the latter using

$$C_{\vec{u}}(r) = K \frac{\sum_{i,j=1}^{N} \vec{u}_i \cdot \vec{u}_j \, \delta(r - r_{ij})}{\sum_{i,j=1}^{N} \delta(r - r_{ij})},$$
 (3)

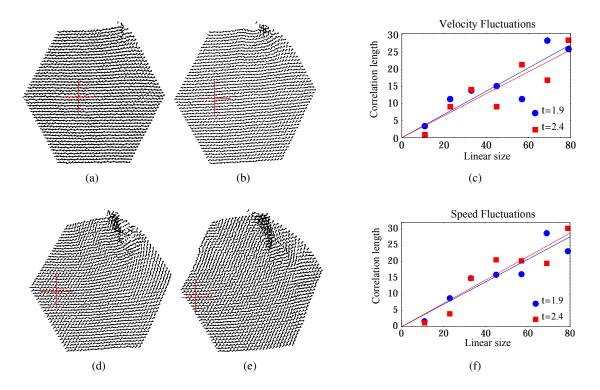

Figure 1: Simulation snapshots at t = 0.5 (a), 1.0 (b), 1.5 (d), and 2.0 (e). Red crosses indicate where the hexagon's center was at t = 0. Correlation lengths of the velocity (c) and speed fluctuations (f) as a function of group sizes at two different times.

and the correlation function $C_s(r)$ for the speed fluctuations using an equivalent expression, but where \vec{u}_i is replaced by s_i and the dot product by multiplication. Here, r_{ij} is the distance between agents i and j, $\delta(\cdot)$ is a smoothed Dirac delta function, and K is a normalizing constant defined so that $C_{\vec{u}}(0)=1$. Both functions must cross zero since s_i and \vec{u}_i have zero mean. We thus define as correlation lengths the first zero-crossing points of $C_{\vec{u}}(r)$ and $C_s(r)$.

We performed the simulations and analysis for hexagonal groups containing $N=91,\ 397,\ 817,\ 1519,\ 2437,\ 3571,$ and 4681 agents, a range slightly larger than in the starling experiments. Correlation functions were computed at t=1.9 and 2.4 (two somewhat arbitrary instants, chosen slightly after the perturbation crosses our largest hexagon) in order to examine the typical correlation lengths and their degree of variation. Panels (c) and (f) display the correlation lengths of the velocity and speed fluctuations, respectively, as a function of the linear size of the group, defined here as the distance between opposing vertices of the undeformed hexagon. While we observed significant variations throughout the dynamics, both quantities are shown to be large and proportional to the group size, as in Cavagna et al. (2010).

Discussion and conclusion The results above show that the scale-free correlations observed in starling experiments are not necessarily due to a critical regime, but can be a natural consequence of position-based interactions among in-

dividuals. Our work also provides a bio-inspired algorithm that can produce coherent, group-level collective motion for robot swarms or other artificial flocks. By implementing the AE model, highly correlated motion dynamics that always span a significant and approximately constant fraction of the group, regardless of its size, can be achieved.

Asynchronous Evolution: Emergence of Signal-Based Swarming

Olaf Witkowski and Takashi Ikegami

University of Tokyo, Japan olaf@sacral.c.u-tokyo.ac.jp

Abstract

Since Reynolds boids, swarming behavior has often been reproduced in artificial models, but the conditions leading to its emergence are still subject to research, with candidates ranging from obstacle avoidance to virtual leaders. In this paper, we present a multi-agent model in which individuals develop swarming using only their ability to listen to each others signals. Our model uses an original asynchronous genetic algorithm to evolve a population of agents controlled by artificial neural networks, looking for an invisible resource in a 3D environment. The results demonstrate that agents use the information exchanged between them via signaling to form temporary leader-follower relations allowing them to flock together.

Introduction

The ability of fish schools, insect swarms or starling murmurations (Figure 1) to shift shape as one and coordinate their motion in space has been studied extensively because of their implications for the evolution of social cognition, collective animal behavior and artificial life (Couzin 2009).

Figure 1: Starling murmuration¹

Swarming is the phenomenon in which a large number of individuals organize into a coordinated motion. Using only the information at their disposition in the environment, they are able to aggregate together, move *en masse* or migrate

towards a common direction.

The movement itself may differ from species to species. For example, fish and insects swarm in three dimensions, whereas herds of sheep move only in two dimensions. Moreover, the collective motion can have quite diverse dynamics. While birds migrate in relatively ordered formations with constant velocity, fish schools change directions by aligning rapidly and keeping their distances, and insects swarms move in a messy and random-looking way (Budrene et al. 1991, Czirók et al. 1997, Shimoyama et al. 1996).

Numerous evolutionary hypotheses have been proposed to explain swarming behavior across species. These include more efficient mating, good environment for learning, combined search for food resources, and reducing risks of predation (Zaera et al., 1996). Partridge and Pitcher (1979) also mention energy saving in fish schools by reducing drag.

In an effort to test the multiple theories, the past decades counted several experiments involving real animals, either inside an experimental setup (Partridge, 1982; Ballerini et al., 2008) or observed in their own ecological environment (Parrish and Edelstein-Keshet, 1999). Those experiments present the inconvenience to be costly to reproduce. Furthermore, the colossal lapse of evolutionary time needed to evolve swarming, make it almost impossible to study the emergence of such behavior experimentally.

Computer modeling has recently provided researchers with new, easier ways to test hypotheses on collective behavior. As it is well known, simulating individuals on machines offers easy modification of setup conditions and parameters, tremendous data generation, full reproducibility of every experiment, and easier identification of the underlying dynamics of complex phenomena.

From Reynolds' boids to recent approaches

In a massively cited paper, Craig Reynolds (1987) introduces the *boids* model simulating 3D swarming of agents called *boids* controlled only by three simple rules:

• Alignment: move in the same direction as neighbours

¹Copyright Walter Baxter and licensed for reuse under this Creative Commons Licence.

- Cohesion: Remain close to neighbours
- Separation: Avoid collisions with neighbours

Various works have since then reproduced swarming behavior, often by the means of an explicitly coded set of rules. For instance, Mataric (1992) proposes a generalization of Reynolds' original model with an optimally weighted combination of six basic interaction primitives². Hartman & Benes (2006) come up with yet another variant of the original model, by adding a complementary force to the *alignment* rule, that they call *change of leadership*. Unfortunately, in spite of the insight this kind of approach brings into the dynamics of swarming, it shows little about the pressures leading to its emergence. Many other approaches are based on informed agents or fixed leaders (Cucker & Huepe 2008, Su et al. 2009, Yu et al. 2010).

For that reason, experimenters attempted to simulate swarming without a fixed set of rules, rather by incorporating into each agent an artificial neural network brain that controls its movements. The swarming behavior is evolved by copy with mutations of the chromosomes encoding the neural network parameters. By comparing the impact of different selective pressures, this type of methodology eventually allows to analyze the evolutionary emergence of swarming.

Tu and Terzopoulos (1994) have swarming emerge from the application of artificial pressures consisting of hunger, libido and fear. Other experimenters have studied prey/predator systems to show the importance of sensory system and predator confusion in the evolution of swarming in preys (Ward et al. 2001, Olson et al. 2013).

In spite of many pressures hypothesized to produce swarming behavior, designed setups presented in the literature are often complex and specific. Previous works typically introduce models with very specific environments, where agents are given specialized sensors sensitive. While they are bringing valuable results to the community, one may wonder about systems with a simpler design.

In addition, even when studies focus on fish or insects that swarm in 3D (Ward et al. 2001) most keep their model in 2D. While the swarming can be considered to be similar in most cases, the mapping from 2D to 3D is found to be nontrivial (Sayama 2012). Indeed, the addition of a third degree of freedom may enable agents to produce significantly distinct and more complex behaviors.

Signaling agents in a resource finding task

This paper studies the emergence of swarming in a population of agents using a basic signaling system, while performing a simple resource gathering task. Simulated agents move around in a three dimensional space, looking for a vital but invisible food resource randomly distributed in the environment. The agents are emitting signals that can be perceived by other individuals' sensors within a certain radius. Both agent's motion and signaling are controlled by an artificial neural network embedded in each agent, evolved over time by an asynchronous genetic algorithm. Agents that consume enough food are enabled to reproduce, whereas those whose energy drops to zero are removed from the simulation.

During the first phase, we observe that agents progressively coordinate into clustered formations, which are preserved through the second phase. Such patterns do not appear in control experiments having the simulation start directly from the second phase, with the absence of resource locations. If at any point the signaling is switched off, the agents immediately stop swarming together. They start swarming again as soon as the communication is turned back on. Furthermore, it is observed that simulations with signaling lead to agents gathering very closely around food patches, whereas the control simulations with silented agents end up with them wandering around erratically.

The main contribution of this work is to demonstrate that collective motion can originate, without explicit central coordination, from the combination of a generic communication system and a simple resource gathering task. A specific genetic algorithm with an asynchronous reproduction scheme is developed and used to evolve the agents' neural controllers. In addition, the search for resource is shown to improve from the agents clustering, eventually leading to the agents gathering closely around goal areas. An indepth analysis shows increasing information transfer between agents throughout the learning phase, and the development of leader/follower relations that eventually push the agents to organize into clustered formations.

The rest of the paper is organized as follows. The next section describes the details of our model. Then simulation settings and results are discussed, before finally drawing a conclusion in the last section.

Model

Agents in a 3D world

We simulate a group of agents moving around in a cubic, toroidal arena of $600 \times 600 \times 600$. The agents rely on energy to survive. If at any point an agent's energy drops to zero, it is immediately removed from the environment. The task for the agents is to get as close as possible to a preset resource spot. By getting close to one of those spots, agents can gain more energy, allowing them to counterbalance the energy losses due to movement and signaling. An agent whose energy drops to zero is removed from the simulation. In this regard, the energy also represents each agent's fitness, and in this paper both terms are used interchangeably.

²Namely, those primitives are collision avoidance, following, dispersion, aggregation, homing and flocking.

The agent's position is determined by three floating point coordinates between 0.0 and 600.0. Each agent is positioned randomly at the start of the simulation, and then moves at a fixed speed of 1 unit per iteration. The direction of motion is decided by two motors controlling Euler angles ψ for pitch (i.e. elevation) and θ for yaw (i.e. heading).

Communication among agents

Every agent is also provided with one communication actuator capable of sending signals with intensities (signals are encoded as floating point values ranging from 0.0 to 1.0), and six communication sensors allowing it to detect signals produced by other agents up to a distance of 100 from 6 directions, namely frontal (0,1,0), rear (0,-1,0), left (1,0,0), right (-1,0,0), top (0,0,1) and bottom (0,0,-1)). The communication sensors are implemented so that every source point in a 100-radius sphere around the agent is linked to one and only one of its sensors. The sensor whose direction is the closest to the signaling source receives one float value, equal to the sum of every signal emitted within range, divided by the distance, and normalized between 0.0 and 1.0.

A neural network inside each agent

The agent's neural controller is implemented by an Elman artificial neural network with 6 input neurons, encoding the activation states of the corresponding 6 sensors, fully connected through a 10-neuron hidden layer to 3 output neurons controlling the two motors and the communication signal emitted by the agent. The hidden layer is given a form of memory feedback from a 10-neuron context layer, containing the values of the hidden layer from the previous time step.

All nodes in the neural network take values between 0.0 and 1.0. All output values are also floating values between 0.0 and 1.0, the motor outputs are then converted to angles between $-\pi$ to π . The activation state of internal neurons is updated according to a sigmoid function.

An asynchronous reproduction scheme

Our model differs from the usual genetic algorithm paradigm, in that it designs variation and selection in an asynchronous way. The reproduction takes place continuously throughout the simulation, creating overlapping generations of agents. This allows for a more natural, continuous model, as no global clock is defined, that could bias or weaken the model.

Every new agent is born with an energy equal to 2.0. In the course of the simulation, each agent can gain or lose a variable amount of energy. At iteration t, the fitness function f_i for agent i is defined by $f_i(t) = \frac{r}{d_i(t)}$ where r is the reward value and d_i is the agent's distance to the

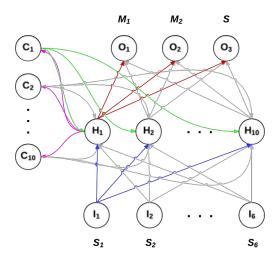

Figure 2: Architecture of the agent's controller, composed of 6 input neurons $(I_1 \ {\rm to} \ I_6)$, 10 hidden neurons $(H_1 \ {\rm to} \ H_{10})$, 10 context neurons $(C_1 \ {\rm to} \ C_10)$ and 3 output neurons $(O_1 \ {\rm to} \ O_3)$.

goal. The reward value is controlled by the simulation such that the population remains between 100 and 500 agents. All the way through the simulation, the agents also spend a fixed amount of energy for movement (0.01 per iteration) and a variable amount of energy for signaling costs $(0.001 \times signal\ intensity\ per\ iteration)$.

The weights of every connection in the neural network (apart from the links from hidden to context nodes, which have fixed weights) are encoded in a genotype and evolved through generations of agents. Each weight is represented by a unique floating point value in the genotype vector, such that the size of the vector is simply equal to the total number of connections in the neural network. The simulation uses a genetic algorithm with overlapping generations to evolve the weights of the neural networks. Whenever an agent accumulates 10.0 in energy, a replica of itself (with a 5% mutation in the genotype) is created and added to a random position in the arena. The agent's energy is decreased by 8.0 and the new replica's energy is set to 2.0. The choice for random initial positions is to avoid biasing the proximity of agents, so that reproduction does not become a way for agents to create local clusters.

Indeed, a local reproduction scheme (i.e. giving birth to offspring close to their parents), leads rapidly to an explosion in population size, as the agents that are close to the resource create many offspring that will be very fit too, thus able to replicate very fast as well. This is why the newborn offspring is placed randomly in the environment.

For our genetic algorithm to be effective, the number of agents must be maintained above a certain level. Also, the computation power limits the population size. The fitness allowed to the agents is therefore adjusted in order to maintain an acceptable number of agents (between 100 and 1000) alive throughout the simulation. In addition, agents above a certain age (5000 time steps) are removed from the simulation, to keep the evolution from standing still.

Results

Emergence of swarming

We observe agents coordinate together in clustered groups. As shown in Figure 3 (top) the simulation goes through three distinct phases. In the first one, agents wander in an apparently random way across the space. Then, during the second phase, agents progressively cluster into a rapidly changing shape, reminiscent of animal flocks³. In the third phase, towards the end of the simulation, the flocks get closer and closer to the goal⁴, forming a compact ball around it.

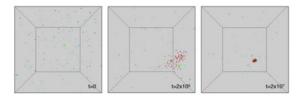

Figure 3: Visualization of the development of a typical run with a single resource spot. The agents start off in a random motion (left), then progressively come to coordinate in a dynamic cluster (middle), and finally flock more and more closely to the goal (right).

Figure 4 shows more in detail the swarming behavior taking place in the second phase. The agents coordinate in a dynamic, quickly changing shape, continuously extending and compressing, while each individual is executing fast paced rotations on itself. Note that this fast looping seems to be necessary to the emergence of swarming, as all trials with slower rotation settings never achieved this kind of dynamics. One regularly notices some agents reaching the border of a swarm cluster, leaving the group, and most of the time ending up coming back in the heart of the swarm.

In spite of the agents needing to pay a cost for signaling (cf. description of the model), the signal keeps an average value between 0.2 and 0.5 during the whole experiment (in the case with signalling activated).

It is also noted that a minimal rotation speed is necessary for the evolution of swarming. Indeed, it allows the agent to

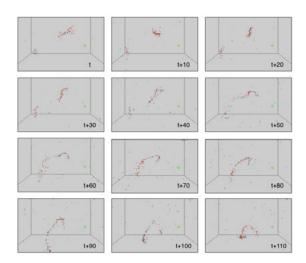

Figure 4: Visualization of the swarming behavior occurring in the second phase of the simulation.

react faster to the environment, as each turn making one sensor face a particular direction allows a reaction to the signals coming from that direction. The faster the rotation, the more the information gathered by the agent about its environment is balanced for every direction.

Neighborhood analysis

We choose to measure swarming behavior in agents by looking at the average number of neighbors within a radius of 100 distance around each agent. Figure 5 shows the evolution of the average number of neighbors, over 10 different runs, respectively with signaling turned on and off. A much higher value is reached around time step 10^5 in the signaling case, while the value remains for the silent control.

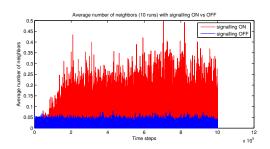

Figure 5: Comparison of the average number of neighbors (average over 10 runs, with 10^6 iterations) in the case signaling is turned on versus off

We also want to measure the influence of each agent on its neighborhood. To do so, the *inward* average transfer entropy

³As mentioned in the introduction, swarming can take multiple forms depending on the situation and/or the species. In this case, the clustering resemble in some aspects mosquito or starling flocking

⁴Even though results with one goal are presented in the paper, same behaviors are obtained in the case of two or more resource spots.

on agent's velocities is calculated⁵ between each neighbor within a distance of 100 and the agent itself. We will refer to this measure as inward neighborhood transfer entropy (NTE). This can be considered a measure of how much the agents are "following" their neighborhood at a given time step. The values rapidly take off on the regular simulation (with signaling switched on), while they remain low for the silent control, as we can see for example on Figure 6.

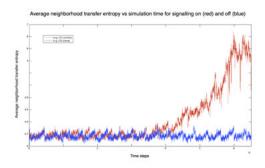

Figure 6: Plot of the average *inward* neighborhood transfer entropy for signaling on (*red curve*) and off (*blue curve*)

Similarly, we can calculate the *outward* neighborhood transfer entropy (i.e. the average transfer entropy from an agent to its neighbors). We may look at the evolution of this value through the simulation, in an attempt to capture the apparition of local leaders in the swarm clusters. Even though the notion of leadership is hard to define, the study of the flow of information is essential in the study of swarms. The single individuals' *outward* NTE shows a succession of bursts coming everytime from different agents, as illustrated on Figure 7. This frequent switching of the origin of information flow can be interpreted as a continual change of leadership in the swarm. The agents tend to follow a small number of agents, but this subset of leaders is not fixed over time.

On the upper graph in Figure 8, between iteration 10^5 and 2×10^5 , we see the average distance to the goal drop to values oscillating between roughly 50 and 300, that is the best agents reach 50 units away from the goal, while other agents remain about 300 units away. On the control experiment graph (Figure 8, bottom), we observe that the distance to the goal remains around 400.

Swarming, allowed by the signaling behavior, allows agents to stick close to each other. That ability allows for a winning strategy in the case when some agents already are successful at remaining close to a resource area. Swarming may also help agents find goals in the fact that they constitute an efficient searching pattern. Whilst an agent alone is subject to basic dynamics making it drift away, a bunch of

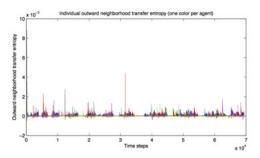

Figure 7: Plot of the individual *outward* neighborhood transfer entropy. Each color corresponds to a distinct agent.

agents is more able to stick to a goal area once it finds it, since natural selection will increase the density of surviving agents around a those areas. In the control experiments without signaling, it is observed that the agents, unable to form swarms, do not manage to gather around the goal in the same way as when the signaling is active.

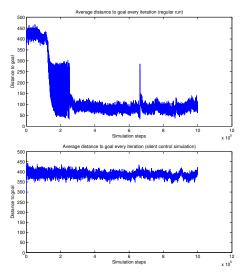

Figure 8: Average distance of agents to the goal with signaling (top) and a control run with signaling switched off (bottom)

Controller response

After simulation, we test neural networks of each swarming agent and qualitatively compare them to non-swarming ones'. We observed that characteristic shapes for the curve obtained with swarming agents presented a similarity (see Figure 9, top), and differed from the patterns of non-swarming agents (see Figure 9, bottom) which were also more diverse. In swarming individuals' neural networks,

⁵The calculations are analogous to Wibral et al. (2013).

patterns were observed leading to higher motor output responses in the case of higher signal inputs. This is characteristic almost every swarming individuals, whereas non-swarming agents present a wide range of response functions. A higher motor response may allow the agent to slow down its course accross the map by executing quick rotations around itself, therefore keeping its position nearly unchanged. If this behavior is adopted in the case where the signal is high, that is in presence of signaling agents, the agent is able to remain close to them.

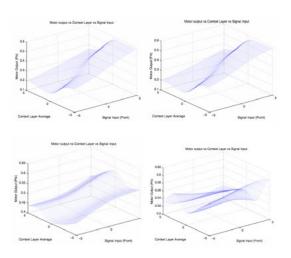

Figure 9: Plots of evolved agents' motor responses to a range of value in input and context neurons. The three axes represent signal input average values (right horizontal axis), context unit average level (left horizontal axis), and average motor responses (vertical axis). The *top* two graphs correspond to the neural controllers of swarming agents, and the *bottom* ones correspond to non-swarming ones'.

Phylogeny

To study the heterogeneity of the population, the phylogenetic tree is visualized (Figure 10). At the center of the graph is the root of the tree, which corresponds to time zero of the simulation, from which start the 200 initial branches. As those branches progress outward, they create ramifications that represent the descendance of each agent. The time step scale is preserved, and the segment drawn below serves as a reference for 10^5 iterations. Every fork corresponds to a newborn agent⁶. Therefore, every "fork burst" corresponds to a period of high fitness for the concerned agents.

On Figure 11, one can observe another phylogenetic tree, represented horizontally in order to compare it to the average

number of neighbors throughout the simulation. The neighborhood becomes denser around iteration 400k, showing a higher portion of swarming agents. This leads to a firstly strong selection of the agents able to swarm together over the other individuals, a selection that is soon relaxed due to the signaling pattern being largely spread, resulting in a heterogeneous population, as we can see on the upper plot, with numerous branches towards the end of the simulation.

The phylogenetic tree shows some heterogeneity, and the average number of neighbors is a measure of swarming in the population. The swarming takes off around iteration 400k, where there seems to be a genetic drift, but the signaling helps agents form and keep swarming.

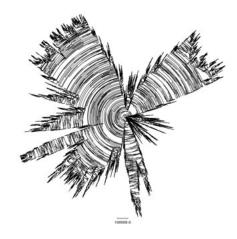

Figure 10: Phylogenetic tree of agents created during a run. The center corresponds to the start of the simulation. Each branch represents an agent, and every fork corresponds to a reproduction process.

Discussion

In our simulation, agents progressively evolve the ability to flock through communication to perform a foraging task. We observe a dynamical swarming behavior, including coupling/decoupling phases between agents, allowed by the only interaction at their disposal, that is signaling. Eventually, agents come to react to their neighbors' signals, which is the only information they can use to improve their foraging. This can lead them to either head towards or move away from each other. While moving away from each other has no special effect, moving towards each other, on the contrary, leads to swarming. Flocking with each other may lead agents to slow down their pace, which for some of them may keep them closer to a food resource. This creates a beneficial feedback loop, since the fitness brought to the agents will allow them to reproduce faster, and eventually multiply this type of behavior within the total population.

⁶The parent forks counterclockwise, and the newborn forks clockwise.

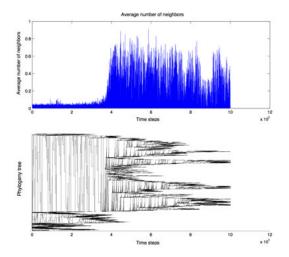

Figure 11: *Top:* average number of neighbors during a single run. *Bottom:* agents phylogeny for the same run. The roots are on the left, and each bifurcation represents a newborn agent.

In this scenario, agents do not need extremely complex learning to swarm and eventually get more easily to the resource, but rather rely on dynamics emerging from their communication system to create inertia and remain close to goal areas.

It should be noted that the simulated population has strong heterogeneity due to the asynchronous reproduction schema, which can be visualized in the phylogenetic tree (Figure 10). Such heterogeneity may suppress swarming but the evolved signaling helps the population to form and keep swarming. The simulations do not exhibit strong selection pressures to adopt specific behavior apart from the use of the signaling. Without high homogeneity in the population, the signaling alone allows for interaction dynamics sufficient to form swarms, which proves in turn to be beneficial to get extra fitness as it has been mentioned above.

The results presented in this paper can be compared to many works in the literature. Ward et al. (2001) and Olson et al. (2013) also show the emergence of swarming without explicit fitness, though those are based on a predator-prey model. The type of swarming obtained with simple pressures is usually similar to the one obtained in this study, that presents the advantage of being based on a very simple system based on resource finding and signaling/sensing. Models such as Blondel et al. (2005), Cucker & Huepe (2008) and Su et al. (2009) achieve swarming behavior based on explicit exchange of information from leaders. Our simulation improves on this kind of research in the sense that agents naturally switch leadership and followership by exchanging information over a very limited channel of communication.

Finally, our results also show the advantage of swarming for resource finding (it's only only through swarming, enabled by signaling behavior, that agents are able to reach and remain around the goal areas), comparable to the advantages of particle swarm optimizations (Kennedy et al. 1995), here emerging in a model with a simplistic set of conditions.

Conclusion

In this work we have shown that swarming behavior can emerge from a communication system in a resource gathering task. We implemented a three-dimensional agent-based model with an asynchronous evolution through mutation and selection. The results show that from decentralized leader-follower interactions, a population of agents can evolve collective motion, in turn improving its fitness by reaching invisible target areas.

Our results represent an improvement on models using hard-coded rules to simulate swarming behavior, as they are evolved from very simple conditions. Our model also does not rely on any explicit information from leaders, like previously used in part of the literature (Cucker & Huepe 2008, Su et al. 2009). It does not impose any explicit leader-follower relationship beforehand, letting simply the leader-follower dynamics emerge and self-organize. In spite of being theoretical, the swarming model presented in this paper offers a simple, general approach to the emergence of swarming behavior once approached via the boids rules.

Extended Abstract

Many prey choose to live, forage, and reproduce in groups — this is one of the most readily-observed phenomena in biology. Group living is potentially costly (because of competitive interactions among other reasons), and the benefits that outweigh these costs are difficult to understand, as they may interact in complicated ways (Krause and Ruxton, 2002). Collective vigilance is one oft-cited benefit of grouping behaviors. This claim relies on the principle that at each moment in time prey must make a choice between two mutually exclusive actions: foraging for food or being vigilant to look for predators. Group foraging potentially allows individuals to increase their foraging efficiency — and therefore their fitness — by sharing the expensive task of looking out for predators. Since isolating such decision-making in biological systems is difficult (particularly on an evolutionary timescale), we use digital organisms to study how this decision is made by groups of prey under the threat of predation.

Decision making in groups can take two different forms. Most computational research has concentrated on homogeneous groups, where every agent has an identical method of making decisions, usually regarding movement (Ward et al., 2001). However, it is also possible for groups to be heterogeneous, with behaviors varying drastically among individuals. A group with both altruistic and selfish members would be an example of such heterogeneity.

Here, we explore the effects of this distinction between homogeneous and heterogeneous group composition in relation to the evolution of vigilance behaviors. In addition, we examine the impact of two reproductive strategies: populations are either iteroparous (reproducing repeatedly) or semelparous (reproducing a single time before they die), which should affect the intensity of selection on antipredatory traits that influence survival to reproductive maturity.

Methods As in previous work, agent fitness is determined in a disembodied simulation, where the agent's goal is to forage as much as possible while surviving predator attacks (Ruxton and Beauchamp, 2008). All agents are in the same group, and group size is varied between experiments to explore its effect. Fitness is equal to the number of updates spent foraging rather than being vigilant. When the simu-

lation is complete, a genetic algorithm generates the next population of genotypes. An agent's genotype codes for a Markov Network in which one output state is the decision to forage or be vigilant (Olson et al., 2013). Currently, this means vigilance levels are defined by probabilities, but future studies could consider more complex outputs (e.g. multiple interrelated strategies), or inputs from a visual system that provides a richer picture of the environment.

In the simulation, vigilance comes into play when a predator attacks. The rate of this attack is relative to the size of the group, so there is no dilution of the attack risk with increasing group size. When the predator appears, it randomly selects one of the prey as its target. The predator then waits for several turns (approximating the time required to close for an attack). If the target is vigilant at some point in this interval, it becomes aware of the predator and has a 90% chance of survival. If the target remains unaware but another prey is vigilant, the target has a 50% chance of survival (i.e., the threat is automatically communicated). If none of the prey are vigilant, the target has a 10% survival rate.

The fitness function can be varied in two ways. First, prey can be evaluated in either homogeneous or heterogeneous groups. In a homogeneous evaluation, one genotype is considered at a time, copies of its agent are made to fill the simulation, and the final fitness of all of these clones is averaged at the end. In a heterogeneous evaluation, genotypes compete against one another and the fitness an agent has at the end of the simulation is its fitness for that generation. Since differing genotypes can evolve to exploit the vigilance of others, thus lowering their own vigilance, we hypothesize that vigilance will be greater in homogeneous populations.

The second method for varying fitness functions is reproductive method. In semelparous treatments, a prey that died during the simulation is assigned a fitness of zero for that entire simulation (i.e., only surviving agents are said to reach reproductive maturity). In iteroparous treatments, dead prey cease to forage but they do not lose the fitness they have acquired during their lifetime (i.e., reproduction is continually occurring in the group). We hypothesize that semelparous treatments select more strongly for survival, therefore they

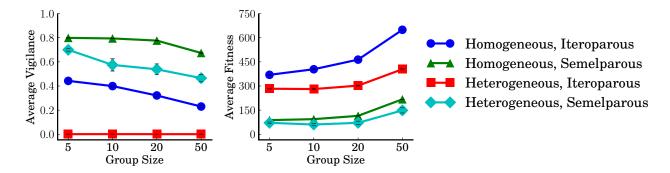

Figure 1: Semelparity and homogeneity select positively for vigilant behavior in prey without interfering with one another. Either treatment is sufficient to select for vigilance, but at least one is necessary. Fitness increases with group size while vigilance decreases, as predicted by the many-eyes hypothesis. Error bars are shown for 95% confidence intervals.

should produce higher levels of vigilance.

Results As shown in Figure 1, agents are more vigilant in semelparous treatments. This finding holds across both homogeneous and heterogeneous populations. In addition, homogeneous populations consistently evolve higher levels of vigilance than heterogeneous populations. We do not take this to mean that cooperative vigilance is impossible in heterogeneous groups, only that vigilance is a less stable strategy when genotypes compete against one another. This conclusion is supported by the evolution of vigilance in heterogeneous, semelparous populations, which shows that vigilance is possible outside of homogeneous conditions.

While homogeneity and reproductive strategy both select positively for vigilance, Figure 1 demonstrates that homogeneity plays the greater role. This can be seen from the lower evolved vigilance levels in the homogeneous, iteroparous populations compared to the heterogeneous, semelparous populations. Homogeneity and reproductive strategy also do not inhibit one another's selective pressure, since the homogeneous, semelparous population evolves the greatest levels of vigilance.

It is possible that some prey could evolve to take advantage of the vigilance of others. Such cheaters would spend most of their time foraging. Naturally, this is only possible in the heterogeneous treatment. We would expect such genotypes, if they exist, to be characterized by significantly higher fitness and lower vigilance values. However, in all cases the most fit organism in the population had vigilance and fitness values closely matching that of the rest of the population. Thus, we posit that this experimental environment is not suitable for the evolution of a stable cheating strategy.

Our general finding that vigilance promotes survival in groups even when it entails a tradeoff with foraging aligns with observational evidence of animals (Lima, 1995), which show higher levels of vigilance in smaller groups. The inverse relationship between vigilance and group size and the

direct relationship between fitness and group size we observed fit the predictions made by one theory on the benefits of grouping, the many-eyes theory (Pulliam, 1973). Such patterns suggest that the advantages of vigilance are a major driver of group living, and may favor living in larger groups in spite of the costs of competition. So far we have not explored such variables as the dilution of predation risk by group size (we explicitly controlled this), the dilution of vigilance costs by relatedness, or the ability to vary levels of vigilance conditional upon an assessment of the risks, but our system provides a platform for exploring such variables.

Swarm Grammars GD: Interactive Exploration of Swarm Dynamics and Structural Development

Sebastian von Mammen, Sarah Edenhofer

Organic Computing, University of Augsburg, Bavaria, Germany {sebastian.von.mammen, sarah.edenhofer}@informatik.uni-augsburg.de

Abstract

We present an interactive simulation of Swarm Grammars (SGs). SGs are an extension of L-Systems, where symbols of the production system are considered agents, whereas the given production rules determine their differentiation or reproduction. Assigning boid properties to the SG agents yields spatial dynamics apt to building structures in space and to collaborate stigmergically. In the presented interactive simulation, we put an emphasis on accessible interactive visuals for shaping the initial configuration of the simulation, to program the agents' perceptual and productive behavioural abilities, to dynamically drive developmental stages and to fine-tune visual structural properties such as colouring and scaling of the utilised developmental building blocks. Our system has been successfully deployed to promote swarm dynamics and developmental processes as important aspects of Artificial Life in a playful way. We present results from deploying the simulation in the context of an event to promote STEM research among high-school girls.

Introduction

Confronted with the challenge of providing an engaging entrance point to Artificial Life research to young high-school students, we decided on implementing an interactive Swarm Grammar (SG) simulation (von Mammen and Jacob (2009)). SGs seemed to be an adequate choice, as they integrate aspects of complex system dynamics—bridging from the behaviour or simple individuals to the emergent properties of large populations—and developmental processes—yielding unique artefacts that allow to trace spatial interaction processes over time.

In order to kindle intrinsically motivated engagement (Koster (2013)), the simulation was devised to (a) establish a relationship between the students, the software and its artefacts. (b) We had to provide accessible means to defining rules and configuring agents so the students could challenge their competence in the actual simulation processes and explore the outcome of their high-level programming ingenuity. (c) The intensity of the students' explorations and design efforts has to result from their voluntary engagement. Accordingly, the simulation provides an open-ended,

directly manipulatable playground environment that is freely and widely accessible as a public, WebGL-driven website¹.

In the remainder of this paper, we present the following aspects of the project. In the next section, we briefly summarise the key concepts from related works that we utilised in the agents' flocking definition and their (re-)production rules. Afterwards, we explain the simulation concept with an emphasis on its visual programming assets. Before concluding this work with a brief summary and an outlook on possible future work, we dedicate one section to presenting select simulation artefacts as well as preliminary user feedback.

Related Work

Our simulation concept has been developed to support the definition of perception and actuation properties of 'boid' agents and the construction, reproduction or differentiation of swarm grammar agents. The deployed mechanics of user interaction and visual programming techniques that will be outlined in the next section, are a translation of the following, underlying geometrical and grammatical relationships.

Boid Flocking

Reynolds (1987) presented the concept of 'bird-oids', or boids. It implements smooth, decentralised steering of swarms of agents based on several 'flocking urges' that emerge from the relationships between an agent and its neighbours. The neighbourhood is determined by the agent's radial field of view (FOV) defined with a maximal distance d_{max} and an angle α , see the annotated screenshot from our simulation in Figure 1.

Neighbours within a minimal distance d_{min} are considered 'too close' and trigger an evasive manoeuvre away from their centre (separation urge). The agent further synchronises its velocity (heading and speed) with the other neighbours (alignment urge) and it accelerates towards their centre (cohesion urge). Coefficients of these acceleration urges determine the emergent flocking behaviour. In addition to

¹http://www.vonmammen.org/SG-GD/

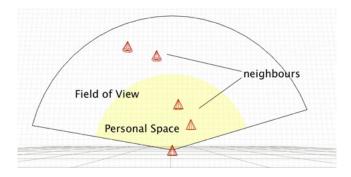

Figure 1: Perception of a 'boid' agent. Agents within its field of view are perceived as neighbours, those within the 'Personal Space' are considered too close, triggering an evasive manoeuvre.

separation, alignment and cohesion, we utilised a correspondingly weighted random vector (random urge) and a global direction vector (direction urge) to steer the individual agent. The acceleration \vec{a}_i of an individual i totals its j neighbour-dependent urges \vec{u}_{ij} , scaled by the individual's weights w_{ij} . The agents' acceleration and flight are kept within reasonable boundaries by maximal values for acceleration, a_{max} , and velocity, v_{max} . For simplicity sake, we chose integration step size $\Delta t = 1$ to infer the updated position p_i' of individual i. The corresponding equation system is listed below; markings denote the sequence of variable updates, $|\vec{x}|$ denotes the norm and \hat{x} the versor of vector \vec{x} .

$$\begin{array}{rcl} \vec{a}_{i} & = & \displaystyle \sum_{j} w_{ij} \vec{u}_{ij} \\ \\ \vec{a}'_{i} & = & \max(a_{max}, |\vec{a}_{i}|) \hat{\vec{a}}_{i} \\ \\ \vec{v}'_{i} & = & \vec{v}_{i} + \vec{a}_{i} \Delta t \\ \\ \vec{v}''_{i} & = & \max(v_{max}, |\vec{v}'_{i}|) \hat{\vec{v}}'_{i} \\ \\ \vec{p}'_{i} & = & p_{i} + \vec{v}''_{i} \Delta t \end{array}$$

In Figure 2, all flocking parameters are shown that the user is encouraged to alter. Similarly to Reynolds' later extensions (Reynolds (2000)), we give the user the ability to introduce novel agents, to change their FOV and flocking weights on the fly and, thus, to interactively guide the emerging flocks.

Swarm Grammar (Re-)Production

Originally, a swarm grammar $SG = (SL, \Delta)$ was conceived as a combination of a rewrite system $SL = (\alpha, P)$ and a set of agent specifications $\Delta = \{\Delta_{a_1}, \Delta_{a_2}, ... \Delta_{a_n}\}$ for n types of agents a_i (von Mammen and Jacob (2009)). The rewrite system SL loosely followed the concept of an L-system with axiom α and production rules P, as described by Prusinkiewicz and Lindenmayer (1990). In the simplest

Figure 2: Boid paramters as displayed to the user and offered for alteration. Changes to the Field of View parameters are immediately reflected by the neighbourhood visualisation of the introspected agent.

form of context-free 0L-systems, each rule has the form $p \to s$, where $p \in \Omega$ is a single symbol over an alphabet Ω , and $s \in \Omega^*$ is a word over Ω . The application of the replacement rule can be conditional, for instance upon a successful stochastic experiment (with specified probability θ) or repeatedly over time (with a specified time period Δt).

Agent specifications may include the flocking parameters described above such as the agents' FOVs and urge weights, as well as characteristic parameters of the geometrical objects they leave behind during their flight. Figure 3(a) shows a representative artefact produced by an early swarm grammar, emphasising the branching structure emerging from the reproduction rules $SL = \{A, \{A \rightarrow BBB, B \rightarrow A\}\}$ in combination with a moderate separation urge.

Later, the rule representation of Swarm Grammars was extended towards quantitative stigmergy (von Mammen and Jacob (2008a)), which (a) allowed to trigger (re-)production, in case a specific environment is perceived and (b) to utilise various static building blocks as well as agent progeny as product. Hence, spatial structures became the outcome of the agents' behavioural interactions rather than simply tracking their flight. A structure built by an extended SG is shown in Figure 3(b).

Interactive Simulation Concept

Our application offers several user interaction mechanisms that support the population and configuration of the simulation space. In order to keep the user interface free from clutter, we decided to omit certain functionalities altogether,

Figure 3: (a) An early SG definition emphasising branching (von Mammen and Jacob (2009)). (b) Artefact built by an extended, stigmergic SG (von Mammen et al. (2009)).

such as the rotation of geometric bodies, and we stripped the UI of any data that would not immediate benefit the target audience, such as the bodies' coordinates. At the backend, too, we pursued a simple but still ambitious management of agent specifications and geometric templates.

Basic Scene Manipulation

Figure 4 shows a close-up of the top-left corner of the main screen. Here, the user can start and stop the simulation. In the pull-down 'templates' menu an agent specification or a static geometry can be chosen to populate the simulation space. Clicking on any object in the scene (initially, there is the ground) places the selected template on top—in this way, the user can stack objects and populate in all three dimensions (Figure 5). Click and drag of an object moves it parallel to the ground. Hovering above an object and pressing the minus key removes an object (we found that the delete or backspace key is frequently assigned to other tasks in standard internet browsers).

Figure 4: The menu of the simulation's main screen. The simulation process can be started, feedback about the current simulation step is provided and a template can be selected to populate the simulation scene.

Right-clicking an object exposes its properties, as seen in Figure 5, and allows the user to change them. Property changes apply to all objects of the same name, which is shown as the top-most entry in the introspection menu to

Figure 5: Templates are placed on top of any clicked, existing objects. Properties of objects in the scene can be introspected and change on right click; an according menu appears in the upper-right corner of the screen.

the right. An alteration of a name triggers the creation of an according, new template in the 'templates' drop-down menu (Figure 4). In this way, the user can create a diverse set of static geometric objects and agent specifications.

Boid flocking parameters, including the field of view, and the (re-)production rules are part of an agent specification. As we offer a visual programming interface to configure some of these properties, the camera positions itself at a predefined distance from the agent when introspected. The dolly animation closing in on an introspected agent is shown in Figure 6.

Rule Editor

During introspection of an agent specification, alterations of the field of view parameters, d_{min} , d_{max} , α , result in an updated visual representation. This immediate reflection helps the user relate the parameter values to actual geometric dimensions and to quickly grasp the variables' relationships. Yet, the visualisation of the field of view plays another, more important role.

Figure 7 shows the view of an introspected agent. Production rules can be specified directly in the vicinity of the agent. In particular, dice, timers, and and arrow-enclosed timers can be dropped, which represent the abstract rule conditions and associate probability θ , point in time t, and time interval Δt variables, respectively. Platonic solids and agents that are placed outside of the introspected agent's FOV are products of a behavioural rule, those inside are considered quantitative, stigmergic conditions. Any such stigmergic conditions are fulfilled, if the according number of objects is perceived by the agent in the neighbourhood or in the personal space, respectively. For production objects, the minute geometric offset from the introspected agent is taken into account. Their displacement as expressed visually in the rule determines their relative placement in the simulation, which resolves the issue of potentially conflicting product placements.

As a consequence of the semantics associated with differently located platonic solids and agents, their placement and movement are diligently tracked and registered. The red bar

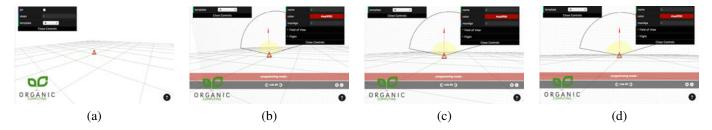

Figure 6: (a) A Swarm Grammar agent placed on the ground. When right-clicked, the camera automatically positions itself at a predefined distance (b-d).

towards the bottom of the screen provides feedback about the user's programming efforts and any corresponding ruleaffecting changes. The grey bar below provides the user with information about the currently displayed rule, to create new rules, to remove existing ones and to browse the complete set of rules of the introspected agent (and its namesakes).

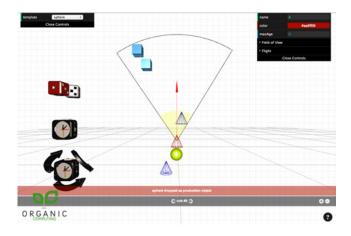

Figure 7: Introspecting an agent specification, sets of production rules may be visually programmed. Abstract conditions, stigmergic conditions, and products of the rules can be placed in the local vicinity of the agents.

Preliminary Feedback & Example Outcomes

In this section, we introduce the circumstances of the first deployment of the interactive simulation presented in this paper, *Swarm Grammars GD*. We provide details on the preliminary feedback we have gathered and we give examples of the artefacts built in this context.

Girls-in-STEM Programme

The concept was conceived while developing contributions to an entertaining and informative programme that aims at encouraging girls to develop and follow their passion for Science, Technology, Engineering and Mathematics (STEM) at the Faculty of Applied Computer Science at the University of Augsburg, Germany. As part of this programme, four groups of roughly ten girls between the ages twelve to fifteen attend four slots of 45 minutes each, offering different contents and activities: 'Autonomous Vehicles', 'Sight-Finder', 'Touch-Robots', and our entry 'Artificial Life'.

Aspects of Artificial Life Research

We identified the following aspects of Artificial Life research that our implementation makes accessible to interested novices in a playful manner.

Similarly to popular simulation environments such as NetLogo (Wilensky and CCL at Northwestern University (2014)), Swarm Grammars GD promotes an agent-based modelling approach. More specifically, it provides direct access, often supported by visual cues and interactive elements, to the parametric properties and sets of "if-then"rules that describe the behaviour of deterministically or stochastically acting, spatially interacting reactive agents (Wooldridge (2009)). When occurring in greater numbers, the interaction of such agents may result in complex feedback cycles, which in turn might lead to emergent phenomena, such as flocking dynamics (von Mammen and Jacob (2008b)) or complex built constructions (Bonabeau et al. (1999)). The means to directly program an individual agent or to simultaneously modify all agents of a certain type allows one to observe and experiment with the relationship between local behaviours and such global emergent patterns, as for instance portrayed by Johnson (2001).

As described in the section on Related Work, the interaction mechanisms that individual agents can perform in *Swarm Grammars GD* are limited to neighbourhood-dependent boid flocking (Reynolds (1987)) and rule-based production as in advanced swarm grammar concepts (von Mammen and Jacob (2009)). Both can be considered concrete concepts of two important Artificial Life themes, namely *collective locomotion* and *developmental models*. We make the first theme accessible by offering the means to visually program an agent's perceptional abilities. It is further promoted as simple construction rules that merely place single three-dimensional objects behind the agents at each simulated step effectively trace the resulting flight dy-

namics, as for instance seen in Figure 8(a).

Regarding the latter theme, developmental models, Swarm Grammars GD touches on the aspects of production, reproduction and differentiation, whereas these processes are triggered by the agents' internal states, effected by timers and stochastic experiments, as well as external stimuli (see our explanations of the visual rule editor above). Motivating differentiation based on locally perceived stimuli, such as the presence of a specific construction template or of a peer of a specific type, enables modelling a mechanism similar to task assignment in social insect societies (Camazine et al. (2003)). Stimulus-dependent construction efforts, on the other hand, allow one to implement sigmergic lines of communication (Grassé (1959)), i.e. indirect communication through the environment. All elements in Swarm Grammars GD, whether they are agents or built objects, have a lifespan attribute which determines the respective element's timely removal from the simulation (the elements are not removed, if this attribute is set to the value 0). Utilising such a timed appearance in combination with stigmergic construction and boid-based cohesion, a simplistic model of Ant Colony Optimisation can be retraced Dorigo (2007).

Presentation Sequence

Despite the intricate modelling options Swarm Grammars GD provide the user with, in the context of a short introduction to young novices, we directed our introductory STEM session to Artificial Life to the foundations of agent-based programming and discussed the intuitively accessible basics of swarm dynamics, construction and reproduction. After brief examples of L-Systems (Prusinkiewicz and Lindenmayer (1990)) and boids (Reynolds (1987)) and their utilisation as special effect techniques by the movie industry (schematic slides and movie snippets), we introduced Swarm Grammars SG hands-on. Following the structure of the above section 'Interactive Simulation Concept', we first explained the main view of the simulation space and basic user interactions to populate it. Next, we briefly demonstrated the exploration potential merely arising from altering various boid parameters. Finally, we detailed the composition of production rules (in this order: producing static geometries, initialising other agent specifications, and adding conditions to the rules). At this point, each group had approximately 25 to 30 minutes at its disposal for exploring and design artificial artefacts and swarm dynamics, under guidance and with feedback if desired. Our offer to print out screenshots of the individually generated artefacts was in good demand, we handed out 24 of them.

Leeway for Improvement

Some weaknesses of the current simulation became obvious during the supervised sessions—especially with respect to choosing reasonable parameter values, including boid urge weights, and configuring abstract production rule conditions such as chance or time steps. One could mitigate the issue of conflicting or ineffective boid parameter sets by offering several presets such as the ones evolved by Kwong and Jacob (2003). Regarding conditional values, if one does not want to drastically limit the expressiveness of rule compositions, warnings could be issued that hint at potentially unreasonable parameters. For instance, agent multiplication at high frequencies quickly exhausts the host computer, if the maximal life span of the agents is relatively high.

While exploring, one student asked how one could program the cubes (as opposed to the agents) to reproduce themselves. This question made clear that the distinction between producing agents and static geometries is arbitrary, not necessary, and possibly not even beneficial for the sake of functional distinction. At least one could expand the computational representation and nullify this rigid distinction. Other, more frequently asked questions were related to increasing the diversity of templates: although creating new templates by entering new names was quickly understood, this mechanism seemed to be too lengthy for supporting the creative diversity in colour and scale some users would have liked to deploy.

Despite the shortcomings of the current implementation, twelve out of a total of 42 participants declared our session and the use of *Swarm Grammars GD* to be the highlight of the whole introductory programme.

Example Artefacts

Figure 8 shows an array of six different Swarm Grammar artefacts programmed by participants of our session. We can identify different classes of structural complexity based on the flocking and production rule complexities of the SG agents. With only minor changes to the default boid flocking parameters (see Figure 2) and continuously dropping geometries, swarm motion is captured by the built artefacts (Figures 8 (a-c)). Agents with distinct construction behaviours—either resulting from differentiated reproduction or from interactively adjusting agent specifications—yield more visually complex structures (Figures 8(d-f)).

Perspective Shots

Unfortunately, as the students did not have much time to explore, play and create, their artefacts were mostly captured from a global perspective, which usually does not emphasise their appealing peculiarities. Figure 9 displays several Swarm Grammar configurations, snapshots of the emergent generative processes and close-ups of the final products set in scene.

In particular, three different Swarm Grammars are shown. The first one, with captions subtitled *cloud*, works based on a simple, unconditional production rule that traces an upwards-flocking agent with a cluster of spheres. The twists and turns triggered by the interplay of several flocking

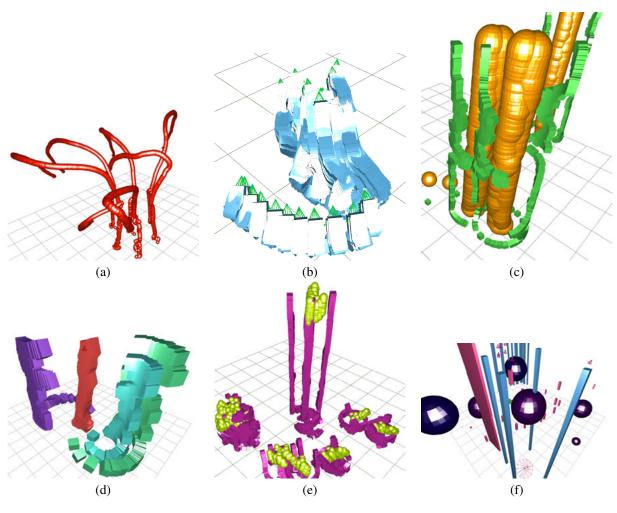

Figure 8: (a-b) Flocking SG agents leaving traces of one platonic solid (red spheres and blue cubes, respectively). (c) Individuals with a strong directional upwards urge leave a trail of two solids, golden spheres and offset green cubes. (d-f) More intricate and diverse structures emerge from building efforts by heterogeneous agent sets.

agents (as seen in Figure 9(b)) are exalted in the close-up by an upwards perspective and light shading. The second example deploys two agents, the first one simply flies upwards, repeatedly creating an offspring of a different kind ($\operatorname{rule}_{wall}^0$). The latter one is pushing hard to the right while continuously dropping cubic solids ($\operatorname{rule}_{wall}^1$) but it is also distracted by its neighbours and thrown off its path by some randomness. The resulting, aligned traces pave a solid uneven wall (close-up_wall); In the third example, a single agent is equipped with two rules, one to establish a continuous trace ($\operatorname{rule}_{tree}^0$) and the second one triggering periodic branching to two sides ($\operatorname{rule}_{wall}^1$). The repeated branching process (process_tree) yields a tree-like structure (close-up_tree).

Conclusion

In this paper, we presented an interactive Swarm Grammar simulation. It has been conceptualised and implemented in order to engage a young audience in Artificial Life concepts, namely swarm dynamics and developmental processes. The simulation attempts to intrinsically motivate the users by keeping the learning-curve as low as possible. At the same time, we challenge the users' competence by attaining a relatively expressive programmable representation, including boid flocking behaviour as well as (re-)production behaviour of Swarm Grammars. The gap between expressive representation and simplicity is bridged by means of visual programming interfaces for configuring the simulation space as well as individual agent behaviours.

We exhibited some of the artefacts designed by a number of high-school students at the age of twelve to fifteen. We suggested several possible improvements to the software based on feedback by the students but also based on observations during supervised hands-on sessions with the simulation. We complemented the display of the students' works by three additional Swarm Grammar examples that explicitly rely on (a) multiple construction elements in single rules, (b) differentiated reproduction, and (c) branching production rules.

In order to further the presented work, we suggest to translate all boid parameters into meaningful interactive visuals. For instance, the line-width of arrows representing various flocking urges could stand for the according, relative weights. Field of View and other visually represented parameters should be readily manipulatable, and not only be altered by means of textual GUIs. The maximal Age of an agent could be visualised by projecting a faded out geometry along its current trajectory. Also, the composition of (re-)production rules could be improved by relating them to the actual environment: the production objects could be projected on top of the actual simulation environment in order to facilitate precise definitions of environmental alterations.

Programmatically, we suggest switching from the current, class-based architecture to a component-based perspective that allows to aggregate behaviours. This would simplify the

template management and provide the flexibility to assign behaviours to arbitrary objects, as asked for by the students.

Four Classes of Morphogenetic Collective Systems

Hiroki Sayama

Collective Dynamics of Complex Systems Research Group Binghamton University, State University of New York, Binghamton, NY 13902-6000, USA sayama@binghamton.edu

Abstract

We studied the roles of morphogenetic principles heterogeneity of components, dynamic differentiation/redifferentiation of components, and local information sharing among components—in the self-organization of morphogenetic collective systems. By incrementally introducing these principles to collectives, we defined four distinct classes of morphogenetic collective systems. Monte Carlo simulations were conducted using an extended version of the Swarm Chemistry model that was equipped with dynamic differentiation/re-differentiation and local information sharing capabilities. Self-organization of swarms was characterized by several kinetic and topological measurements, the latter of which were facilitated by a newly developed network-based method. Results of simulations revealed that, while heterogeneity of components had a strong impact on the structure and behavior of the swarms, dynamic differentiation/re-differentiation of components and local information sharing helped the swarms maintain spatially adjacent, coherent organization.

Introduction

Self-organizing behaviors of biological collectives have been subject to many scientific inquiries (Reynolds, 1987; Ben-Jacob, Cohen & Gutnick, 1998; Parrish & Edelstein-Keshet, 1999; Camazine et al., 2000; Sole & Goodman, 2000; Vicsek & Zafiris, 2012). They have also been enthusiastically applied to engineering problem solving as a new paradigm and methodology for decentralized, distributed problem solving by collaborative artificial agents (Kennedy & Eberhart, 1995; Bonabeau, Dorigo, & Theraulaz, 1999; Leonard & Fiorelli, 2001; Dorigo et al., 2001–2005; Pfeifer, Iida, & Bongard, 2005; Engelbrecht, 2005; Baldassarre, Parisi, & Nolfi, 2006; Braha, Minai, & Bar-Yam, 2006; Doursat, 2008, 2011). Typical assumptions made in the existing literature are that the system components interact with each other mostly locally and make decisions at individual levels, which eventually leads to the emergence of non-trivial (and potentially useful) macroscopic behaviors. Those models have been successful in reproducing various self-organizing patterns and adaptive functionalities.

However, theoretical models used in earlier studies were predominantly focused on homogeneous physical collectives and animal populations. While their simplicity is by itself a virtue in some regard (Vicsek & Zafiris, 2012), they are often too simple to capture more complex phenomena seen in real-world biological collectives, such as multi-cellular organisms' morphogenesis and physiology, termite colony building and maintenance, and growth and self-organization of human social systems. These systems operate with highly sophisticated within-system regulation mechanisms, or "programs" (Doursat, 2008, 2011). What are common among those real-world complex biological collectives are heterogeneity of components, dynamic differentiation/re-differentiation of components (i.e., dynamic switching of component types/roles), and local information sharing among components that influence their differentiation. These morphogenetic principles are often absent in earlier models of biological collective behaviors, and they have not been fully utilized in engineering applications either. Here we define a morphogenetic collective system as a system made of a large number of components that self-organize to form nontrivial structures and behaviors using these morphogenetic principles.

There is growing literature of analytical and numerical studies on self-organizing behavior of biological collectives (Vicsek & Zafiris, 2012; Vicsek et al., 1995; Mogilner & Edelstein-Keshet, 1998; Kunz & Hemelrijk, 2003; Hemelrijk & Kunz, 2005; D'Orsogna et al., 2006; Szabo et al., 2006; Chuang et al., 2007; Newman & Sayama, 2008; Paley et al., 2008; Chate et al., 2008; Romanczuk, Couzin, & Schimansky-Geier, 2009; Tian et al., 2009; Bernoff & Topaz, 2011). It is repeatedly reported that there are a small number of universal classes of collective behaviors, such as disordered, highly ordered, rotational, critical, and jamming patterns, as well as various forms of phase transitions between those classes (Vicsek & Zafiris, 2012). Most of these results are based on the assumption that collectives are homogeneous in terms of their components' kinetic and behavioral properties. Within-population variations are rarely considered in those theoretical models.

There are some studies that considered the effects of heterogeneity within biological collectives. Graves et al. studied mixed-species bird flocks in Amazonia and created a computational model of them (Graves & Gotelli, 1993). More recently, Couzin et al. studied self-sorting of a fish school caused by physical variations among individuals (Couzin et al., 2002). His group also studied collective decisions of a swarm influenced by a small number of informed individuals, or leaders (Couzin et al., 2005). We also proposed the Swarm Chemistry model (Sayama, 2009, 2010, 2012a,b) to explore self-organization of swarms made of kinetically distinct types of particles. However, these studies still assumed that within-population variations are variations of fixed individual properties. None of them considered a more sophisticated form of dynamic, adaptive changes of behavioral rules of individuals within a population, potentially through local communication and information sharing.

When one looks at real-world biological collectives, there are a number of examples where more complex forms of heterogeneous collectives produce highly intricate patterns and behaviors that look almost self-evidently "designed" by someone or something (Doursat, 2008, 2011; Turner, 2007). Such instances can be found at every scale in biology. For example, Ben-Jacob et al. reported very complex, heterogeneous, even intelligent, information processing and motion control taking place in bacteria societies (Ben-Jacob, Cohen & Gutnick, 1998; Ingham & Ben-Jacob, 2008; Ben-Jacob, 2009). Social insects are another well-studied example, where dynamic switching of different roles driven by local information sharing realizes highly efficient division of labor (Camazine et al., 2000; Bonabeau, Dorigo, & Theraulaz, 1999; Bonabeau et al., 1997; Campos et al., 2000; Beshers & Fewell, 2001). Among the most interesting and complex examples are the incredibly sophisticated, large-scale mounds built and maintained by termites (Turner, 2000, 2007, 2011). A termite mound operates as if it were a carefully designed and fully integrated physiological system, inside which individual termites "differentiate" to play various different roles. The complexity of such realworld biological collectives were not fully captured in the earlier literature of collective behaviors mentioned above.

Four Classes of Morphogenetic Collective Systems

As briefly reviewed above, the dynamics and capabilities of different types of morphogenetic collective systems are yet to be fully understood. Recent increase of studies that incorporate at least part of the morphogenetic principles indicates the promising nature of this direction of research. In order to systematically study the effects of each of the morphogenetic principles, here we propose the following four distinct classes of morphogenetic collective systems, which are obtained by incrementally introducing morphogenetic principles to agents' behavioral and communication capabilities

(Fig. 1):

- A. *Homogeneous collectives*, where agents' behaviors are determined by a globally defined, uniformly applicable function of observations.
- B. *Heterogeneous collectives*, where an agent's behavior is determined by a function of observations specified by the agent's static state or type.
- C. Heterogeneous collectives with dynamic differentiation/ re-differentiation, where the heterogeneity of agent behaviors is created and dynamically maintained by transitions of agents' internal states. Agents' state transitions are also determined by a function of observations and states.
- D. Heterogeneous collectives with dynamic differentiation/ re-differentiation and local information sharing, where agents can share information (internal states and their observations) with local neighbors, in addition to all the above capabilities.¹

Our rationale in defining these four classes is that each morphogenetic principle requires the precedent one. Namely, differentiation/re-differentiation requires multiple states or types of components (heterogeneity), and information sharing would make sense only if agents could change their behaviors according to it (differentiation/re-differentiation). We thus argue that these four classes should represent a natural, straightforward hierarchy of morphogenetic collective systems, arranged in the ascending order of their organizational complexity.

In this classification, Class A includes traditional collective behavior models, including Boids (Reynolds, 1987) and its variants that use homogeneous swarms. More recent models that use heterogeneous swarms (Couzin et al., 2002, 2005; Sayama, 2009, 2012a) belong to Class B. Examples that may be close to those of Class C are the variants of Swarm Chemistry (Sayama, 2010, 2011; Sayama & Wong, 2011) that implemented stochastic differentiation/redifferentiation of agents, though it was not driven by any state-transition function and thus not dynamical or adaptive. Finally, real biological/social morphogenetic systems—such as embryogenesis of multicellular organisms, colonies of eusocial insects and cities in human civilizations—are most likely in Class D. Several models proposed in Morphogenetic Engineering (Doursat, Sayama, & Michel, 2012) also belong here. However, we are not aware of any well established model of swarm-based collective behaviors that belong to this class.

¹Here we consider information sharing as explicit signal transmission among agents to share externally unobservable information about their internal states and observations with local neighbors. This should not be confused with kinetically transferred information theoretic waves propagating in swarms that were studied in recent literature (Wang et al., 2012).

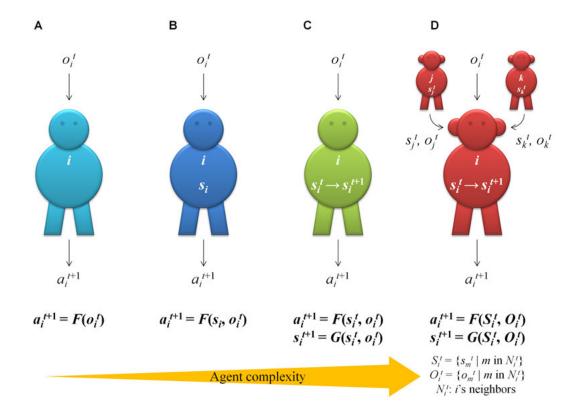

Figure 1: Four classes of morphogenetic collective systems proposed in this paper. Variables s_i , o_i and a_i represent the internal state of agent i, the observation it receives from the environment, and the corresponding action it takes (e.g., acceleration), respectively. A: Homogeneous collectives. Agents' behaviors are determined by a function of observations, $F(\circ)$. B: Heterogeneous collectives. Each agent has its own static state (s_i) , and F takes s_i as an additional argument as well as o_i . C: Heterogeneous collectives with dynamic differentiation. Agents' states can dynamically change according to another function, $G(\circ)$. D: Heterogeneous collectives with dynamic differentiation/ re-differentiation and local information sharing. Arguments of the functions are sets of s_i and o_i within the agent's neighborhood, which represents the local information sharing.

Model: Morphogenetic Swarm Chemistry

To study qualitative and quantitative differences in possible morphologies and behaviors between the four classes, we have developed a mathematical model of morphogenetic collective systems by implementing new rule-based state transition and local information sharing capabilities in the Swarm Chemistry model (Sayama, 2010, 2012b). Swarm Chemistry is naturally suitable for this research task because it already can represent both homogeneous and heterogeneous collective systems in its model framework.

In the extended model, the design of a swarm is specified in three parts: a recipe \mathcal{R} , a preference weight matrix U, and a local information sharing coefficient w. Definitions of these parts are as follows:

Recipe \mathcal{R} : A list of different kinetic parameter settings for multiple swarm states. Each entry in a recipe is composed of a relative frequency of a particular state within the

swarm and its kinetic parameter settings (e.g., local perception range, normal speed, strengths of kinetic forces, etc.). This part of the specification is the same as in our earlier studies (Sayama, 2009, 2010).

Preference weight matrix U: A $n \times (n+5)$ rectangular real-valued random matrix where n is the length of the recipe, i.e., the number of possible states of agents in a swarm. Its contents represent how each observation component (defined later) affects the agent's preference for a particular state choice.

Local information sharing coefficient w: A real number in [0, 1], which determines how much information about the neighbors' states and observations are to be shared and incorporated into the agent's own state transition.

Each agent in a swarm in this extended model has its own state s_i , in addition to position x_i and velocity v_i . The movement and state transition of agents is simulated as follows:

- **Step 1.** An agent computes its action (acceleration) based on its neighbors' relative positions and velocities using the standard Swarm Chemistry simulation algorithm (Sayama, 2009).
- **Step 2.** Before making any actual movement, the agent also computes an (n + 5)-dimensional *observation vector* o_i that summarizes the situation the agent is in. More details of this vector will be discussed later.
- **Step 3.** Once all the agents computed their actions and observation vectors, each agent updates its velocity according to the computed acceleration, and then moves using the updated velocity.
- **Step 4.** The agent computes a *state preference vector* $u_i = (1-w)Uo_i + wU\langle o \rangle_i$, where $\langle o \rangle_i$ is the average of observation vectors of other agents in the local neighborhood. If there are no other agents found in the neighborhood, $u_i = Uo_i$ regardless of w.
- **Step 5.** The agent checks if the s_i -th component of u_i , $u_i(s_i)$, is negative. If this is the case, it means that its current state is not preferable in the current situation, and therefore the agent attempts, with probability $1 \exp(u_i(s_i))$, to choose a new state. A new state will be chosen as the next value of s_i , via a roulette selection where $\exp(u(s))$ is used as the selection weight for state s_i .

The observation vector o_i plays an important role in this model. While there are many choices for how to construct an observation vector, we used the following definition as an initial step of our investigation. The first n components of o_i are all 0's except for the s_i -th component that is set to 1. This part embeds the information about the agent's current state into the vector so that it can be superposed and averaged with other agents' states. The remaining five components of o_i are as follows:

- $|\langle x \rangle_i x_i|^2/R_i^2$: Square of the relative distance from the average position of other agents in the neighborhood $(\langle x \rangle_i)$. R_i is the perception range in the parameter set the agent is currently using. If there are no other agents nearby, this is set to 0.
- v_i^2/v_{in}^2 : Square of the ratio of the agent's current velocity and the normal velocity (v_{in}) in the parameter set the agent is currently using.
- $\langle v \rangle^2 / v_{in}^2$: Square of the ratio of the neighbors' average velocity ($\langle v \rangle$) and the normal velocity in the parameter set the agent is currently using. If there are no other agents nearby, this is set to 0.
- $|\langle v \rangle_i v_i|^2/v_{in}^2$: Square of the relative difference in velocity between the agent and its neighbors. If there are no other agents nearby, this is set to 0.

• 1: A constant term.

Although it is a highly constrained, mathematically stylized formulation, this extended Swarm Chemistry model can still describe a wide variety of morphogenetic collective systems, including the four classes proposed in this paper. Specifically, including only one parameter set in $\mathcal R$ and letting U=0 and w=0 will make a Class A swarm. Including multiple parameter sets in $\mathcal R$ with U=0 and w=0 will make a Class B swarm. A Class C swarm will be obtained by additionally adopting a non-zero matrix for U while w=0. Finally, a Class D swarm will be obtained by adopting non-zero U and w.

Experiments

We conducted systematic Monte Carlo simulations to see if there were any significant differences in the dynamics of morphogenetic collective systems among the four classes. Specifications of swarm designs were configured as follows:

- The number of agents was fixed to 300 for all cases.
- The number of possible agent states n was set to 1 for Class A swarms, or otherwise $\xi + 2$ where ξ is a random integer sampled from a Poisson distribution with mean 1.
- Recipe \mathcal{R} was created by sampling each kinetic parameter's value from a uniform distribution between 0 and the parameter's maximum value defined in (Sayama, 2009). The relative frequencies of different parameter settings were determined by randomly dividing 300 into n portions.
- Preference weight matrix U was set to all 0's for Class A and B swarms. For Class C and D swarms, each component of U was sampled from a normal distribution with mean 0 and standard deviation 0.1.
- Local information sharing coefficient w was set to 0 for Class A, B and C swarms, while it was sampled from a uniform distribution between 0 and 1 for Class D swarms.

Five hundred independent simulation runs were conducted for each class. Each run was initialized with 300 agents whose positions were randomly distributed in a two-dimensional 300×300 (in arbitrary unit) square area and whose velocities were set to 0, and then simulated for 400 time steps. In each time step during the second half of the simulation (t=201-400), the following properties were measured from the agents' positions and velocities:

- Average speed of the swarm as a whole $(|\langle v \rangle|, \text{ where } \langle \ldots \rangle)$ denotes an average over all the agents hereafter unless noted otherwise).
- Average of absolute speed of agents $(\langle |v| \rangle)$.

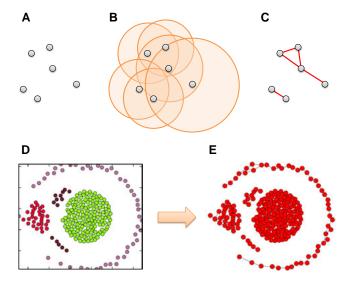

Figure 2: Construction of networks from swarms. Top: Illustration of the algorithm. A: Spatially distributed agents. B: Ranges of neighbor recognition drawn around the agents. The radius of each range is αd_i (see text). C: Resulting network where pairs of agents that mutually recognize each other as neighbors are connected. Bottom: An example of network construction from a simulated swarm. D: Original swarm snapshot. E: Network constructed from agent positions in D.

- Average angular velocity of the swarm as a whole $(\langle (x-\langle x\rangle) \times v/|x-\langle x\rangle|^2\rangle)$.
- Average distance of agents from center of mass $(\langle |x \langle x \rangle| \rangle)$.
- Average pairwise distance $(\langle |x_1 x_2| \rangle$, where x_1 and x_2 are positions of two randomly sampled agents; the average in this case was over 10,000 sampled pairs).

In addition, topological properties of the swarm morphology were also measured. For this task, we constructed a network for each swarm at each time step during the measurement period by connecting agents that were spatially close to each other. More specifically, we first measured a characteristic "neighbor" distance d_i for each agent by calculating the mean of its distances to its k nearest neighbors. The agent then recognized all other agents within distance αd_i as its "neighbors". Once this was done for all agents, the pairs of agents that mutually recognized each other as "neighbors" were actually connected. We used k=2 and $\alpha=1.7$, which were empirically chosen to approximate cluster structures recognized visually by human experimenters. Figure 2 shows examples of this network construction process.

For each swarm converted to a network, we measured the following topological properties:

• Number of connected components.

- Average size of connected components.
- Homogeneity of sizes of connected components. This was measured by the normalized entropy in the distribution of sizes of connected components. If there was only one connected component, this was set to 1.
- Size of the largest connected component.
- Average size of connected components smaller than the largest one. If there was only one connected component, this was set to 0.
- Average clustering coefficient.
- Link density.

Altogether, we obtained time series of 5+7=12 measurements from each simulation run. These time series were further summarized by calculating their respective mean and standard deviation over time. As a result, the structure and behavior of each swarm was characterized by $2\times 12=24$ outcome variables. Finally, a visual image of the swarm at the end of the simulation (t=400) was also recorded for visual inspection of the swarm's topology.

The simulator was implemented in Python using NetworkX (Hagberg, Schult, & Swart, 2008) and PyCX (Sayama, 2013). The code is available upon request.

Results

Simulation results are summarized in Table 1, where medians of 24 outcome variables were shown for each class together with *p*-values obtained using the Kruskal-Wallis median test between the four classes. Statistically significant differences were detected for most of the outcome variables, especially for topological outcome variables, which demonstrates the effectiveness of our network-based topology characterization method. Most of the variables with statistical significance showed clear differences between Class A (homogeneous) and other (heterogeneous) swarms. The temporal mean of the average clustering coefficient was the only outcome variable that did not show statistically significant differences between the classes. This metric may be primarily determined by constraints built in our simulation or network construction algorithms.

We found several notable patterns in Table 1. First, the medians of Class A swarms consistently took the lowest values among the four classes with regard to the temporal standard deviations of measurements (lower half of Table 1). This indicates that the interactions between different types of agents helped produce dynamic behaviors, causing temporal fluctuations of their macroscopic properties. Second, there were clear differences between Class B (with no state

²Visual snapshots of the swarms' final configurations for each of the four classes are also available online at http://bingweb.binghamton.edu/sayama/SwarmChemistry/.

Table 1: Comparison of medians of 24 outcome variables between four classes of morphogenetic collective systems. The p-values of the Kruskal-Wallis median test were shown in the rightmost column (*: p < 0.01, **: p < 0.001, ***: p < 0.0001). Variables with statistically significant differences were highlighted in color (yellow: high, cyan: low). The intensity of color is adjusted according to the p-value of the variable and the distance from overall average. The top half shows temporal means of the 12 measurements while the bottom half shows temporal standard deviations of the 12 measurements.

transitions) and Classes C & D (with state transitions) regarding temporal standard deviations of the average distance of agents from the center of mass and the average pairwise distance. This is likely due to the fact that, while Class B swarms tend to disperse into smaller clusters easily, agents of Class C & D swarms can stay together and maintain spatially adjacent, coherent organization more often, because adaptive state transitions help initially incompatible agents assimilate into kinetically compatible types.

Finally, we noticed a consistent trend in a number of the outcome variables that the properties of Class C & D swarms sat somewhere in between those in Class A and Class B. This could also be understood in that dynamic state transition, possibly driven by local information sharing, has enabled swarms to adaptively achieve coherence in their structures and behaviors. However, the results also indicate that

the swarms in Classes C & D did not simply turn into a more homogeneous state like Class A ones, because nearly all the topological outcome variables showed significant differences between Class A and Classes C & D. Therefore, this apparent trend found in morphogenetic collective systems in Classes C & D must be understood not as simple homogenization but as an emergent shift of higher-level system properties.

Conclusions

In this paper, we proposed a classification of morphogenetic collective systems based on the absence or presence of three morphogenetic principles: heterogeneity of components, dynamic differentiation/re-differentiation of components, and local information sharing among components. Monte Carlo simulations with an extended morphogenetic

Swarm Chemistry model demonstrated that, while heterogeneity of components had a strong impact by itself on the structure and behavior of the swarms, the other two morphogenetic principles, i.e., dynamic differentiation/redifferentiation of components and local information sharing, greatly contributed to the maintenance of spatially adjacent, coherent organization of swarms. Interestingly, many outcome measurements of Class C and D swarms fell somewhere in between those of Class A and Class B. This result indicates that the dynamic, adaptive state transition of components possibly driven by their mutual information sharing is playing an essential role in achieving structural and functional integration of biological and social collectives.

The present study has several fundamental limitations. First, the dynamics of swarms were explored only through a limited number of random parameter sampling and analyzed only using simple median comparisons. It was a reasonable first step of exploration when nothing was known about the model, but this approach would not be able to characterize behavioral diversity and richness of each class of systems or to discover non-trivial behaviors that would be statistically rare but unique and interesting. To fully explore and understand the limit of dynamical diversity of each class, more sophisticated evolutionary or other population-based search methods should be conducted. Now that we have 24 outcome metrics defined, we can try evolving morphogenetic collective systems toward a certain area in this metric space, to examine how closely the swarms of each class can achieve the target properties.

Second, the model we used in this study (morphogenetic Swarm Chemistry) was developed using somewhat arbitrary design decisions. The behavioral rules were exactly the same as those used in previous swarm models, which were limited to agents' acceleration only. The state transition functions were defined in a rather simple and linear fashion using a product of a preferential weight matrix and an observation vector. Moreover, the variables included in the observation vector were chosen without substantial justification. We will need to consider adopting more open-ended, nonlinear forms of representations for observations, state transitions and agent behaviors. We plan to apply genetic programming (Banzhaf et al., 2000) or other symbolic evolutionary search methods (Bongard & Lipson, 2007; Schmidt & Lipson, 2009) to overcome this limitation in the future.

Finally, the scope of the experiments was limited only to "free" self-organization of collectives without any stimuli or constraints. Exposing swarms to such external conditions and measuring their adaptive responses will further clarify the functional differences between different classes of morphogenetic collective systems.

Can active perception generate bistability?

Heterogeneous collective dynamics and vascular patterning

Abstract

During morphogenesis (the generation of form), biological cells, agents or robots must collectively coordinate where and when to move. How to solve such complex, spatial problems in a timely manner, is fundamental to survival in biological organisms, though temporal regulators are largely unexplored. We take the generation of new blood vessel networks (angiogenesis) as our case study system, where tissues low in oxygen stimulate endothelial cells "ECs" (the inner lining of blood vessels) to grow new network branches. This requires ECs to take on heterogeneous states by collectively competing with one another for migratory status via lateral inhibition.

We propose here that the traditional "decide then move" perspective of cell behavior in angiogenesis may miss a key temporal regulator as it is too slow to account for the rapid, adaptive assignment of heterogeneous cell states. Here we show that a "move and decide" view may provide a better account. In a study focused on an individual EC in a simulated collective, we find that active perception (sensorimotor feedback) can generate bistability through migration-induced cell shape changes. We further exemplify that when parameters affecting active perception are modulated, bistability is lost in the single cell. As a consequence, active perception can directly modulate collective decision timing.

Introduction

Collective behavior during morphogenesis requires timely coordination of many autonomous agents, which becomes increasingly complex if the task requires agents have heterogeneous and adaptive phenotypes. Understanding collective coordination mechanisms holds great promise for morphogenetic engineering of well-adapted robot designs (Doursat et al 2012). To this end, the vasculature in living systems is a perfect case study. New vessels grow and remodel in a dynamic adaptive way to maintain a network with near-intimate contact to every cell in the body, required due to the diffusion limit of Oxygen (Aird 2005). When new vessel growth (angiogenesis) is needed, e.g., in development or wound healing, endothelial cells (ECs) lining blood vessel tubes adaptively respond to the release of diffusing growth factors from hypoxic (low in oxygen) tissue. The ECs then collectively coordinate such that some cells migrate and lead new tubular branches ("sprouts"), while others line the tube walls and ensure that the branches are well spaced (Geudens and Gerhardt 2011) (Fig. 1a). The selection of these two states

- "active" or "inhibited" cell movement - is known to be coordinated by Notch-driven "lateral inhibition", where cells battle to inhibit their neighbors (Hellström et al 2007, Jakobsson et al 2009). Lateral inhibition is known to generate stable alternating patterns of on and off cell states in many systems, hereafter referred to as a Salt and Pepper pattern "S&P pattern" (Collier et al 1996). Recently we showed, via an integrated *in silico* and *in vivo* approach, that cell states are not fixed once selected, but rather dynamically adapt and flip throughout angiogenesis (Bentley et al 2009; Jakobsson et al 2010; Bentley et al 2014a). This occurs when ECs 1) meet new neighbors during branch fusion (required to form

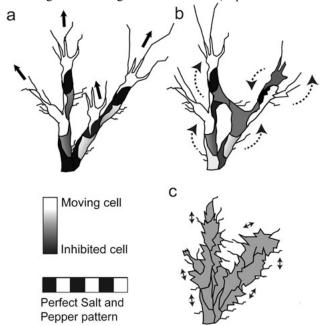

Figure 1. a) Endothelial cells, initially all the same, collectively coordinate to become heterogeneous when stimulated to grow new blood vessel branches. Some cells move, leading new sprouts, others are inhibited, lining the branch and keeping them regularly spaced. The optimal spatial arrangement is a "salt and pepper" (S&P) pattern (alternating states). b) During branching the branches fuse to forming new loops of the network and cells interchange positions. c) If reassignment of states is not rapid the system will fall into homogenous phases as the states are still deciding, disrupting well spaced branching and thickening vessels.

network loops and support blood flow; Fig 1b) (Bentley et al 2009) and 2) rearrange their positions in the collective (Jakobsson et al 2010). Thus, the cellular collective must be capable of rapidly re-establishing the S&P pattern of behaviors in the face of local neighborhood changes, to keep the network branching structure optimized. Otherwise, cells would drift into a "half-way house" state of homogenous movement (Fig. 1c). Lack of differential movement has been shown to disrupt branching as cells hypersprout instead (Hellstrom et al 2008), and has been implicated in abnormal vessel thickening in disease (Bentley et al 2014a). Here we ask, is there an extra dimension of temporal regulation that keeps the system from lingering in a homogeneous state as the process unfolds.

Do cells "Decide then Move" or "Move and decide"?

In Biology, signaling cascades regulating cell behavior are usually presented in a feed-forward manner (Fig. 2a). E.g. ECs are selected as migratory collectively, by Notch lateral inhibition and then those selected will migrate, they "decide then move". However, the relative timing of events indicates that things may, in fact, be more complex.

Lateral inhibition communication between the ECs can be summarized as follows: each cell detects a diffusing stimulatory signal from the hypoxic tissue, primarily Vascular Endothelial Growth Factor (hereafter input signal, "P") by activation of its VEGFR receptors (hereafter sensors, "S"). Sensor activation leads to the up-regulation of the ligand Dll4 ("D"), which then binds to and activates Notch receptors ("N") on neighboring cells. When N is active, the cell downregulates S. Several amplification cycles of this pathway then leads to one cell inhibiting the other's ability to sense, more than the inhibition it, itself, receives (see Figs. 2c-e).

The same sensors also trigger the migratory response of the cell, by locally activating the actin cytoskeleton to first polymerize, generating long thin membrane protrusions called "filopodia" that reach into the environment. Second, actomyosin contractions and adhesion dynamics propel the cell forward. Thus a cell that is more inhibited by Notch signaling, will have less sensors and so will be less migratory (the "inhibited" state).

Lateral inhibition requires gene regulatory changes in the nucleus and protein synthesis, which can take on the order of hours. While faster than multiple cycles required for lateral inhibition, a full migratory response (e.g., where single cells rearrange their positions) also occurs on the time-scale of hours (Jakobsson et al 2010). However, the *initial* migratory response of filopodia growth occurs more rapidly (on the order of minutes) and locally (at the cell surface), without the need to alter gene expression. It is thus logical to assume that the cell shape changes (filopodia) and early movements of the cells membrane during the initial stages of migration will proceed ahead of the established collective decision making process of lateral inhibition.

Consequently, we propose a "move and decide" strategy better captures the process.It is important to note that, the sensors themselves move rapidly during motion, as they reside on the deforming membrane surface. As filopodia extend and retract, sensors are moved to new locations in the environment, continually changing their input (Fig 2c). If the environment contains a gradient, this process has been indicated to speed up collective decision making (Bentley et al 2008). However, the exact reason for this has not been

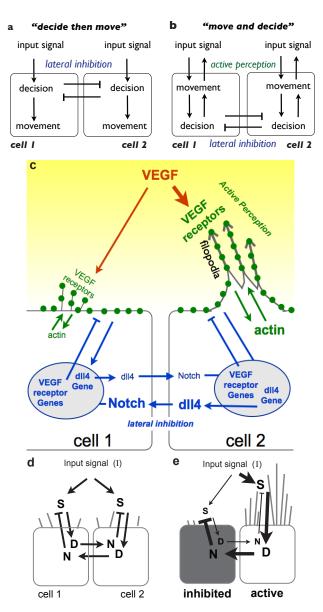

Figure 2. a) traditional feed-forward view of cell behavior regulation in biology termed here a "decide then move" strategy. b) The alternative "move and decide" strategy. c) Signaling pathways involved in blood vessel selection of heterogeneous movement behaviors. Green dots indicate that sensors (VEGFR receptors) reside on the cell membrane, which is deformed and moved as actin polymerizes to form filopodia creating a sensorimotor loop (active perception) d-e) simplified model of (c) S = sensors, D = Dll4, N = Notch, I = input signal. Overtime cells battle back and forth to inhibit each other with one eventually acquiring more filopodia and inhibiting its neighbor more.

established. Here we propose that filopodia act as a means to perform *active perception* of the tissue environment, similar to the proposition that flagella motion confer sensorimotor dynamics and indeed minimal cognition to migrating E. coli cells (Van Duijn et al 2006). While the importance of embodiment in vascular morphogenesis has recently been highlighted (Bentley et. al., 2014b), here we further posit that such active perception confers *bistability* to the active/

inhibited states, rather than the other way around, as currently thought.

An ability to continually adapt and inform our decision making as we move through and experience more of our environment via active perception is known to confer an advantage to decision making, with many studies in robotics and child development e.g. Piaget (1967), Pfeifer (1997) and Beer (2000). As Dewey (1896, pp.137-138) so elegantly put:

We begin not with a sensory stimulus, but with a sensorimotor co-ordination... In a certain sense it is the movement, which is primary, and the sensation which is secondary..."

To establish whether active perception feedback by individual ECs in a "move and decide" strategy may confer robustness and optimize timing of collective decisions, we consider first a tightly controlled, single EC scenario, where collective coordination by lateral inhibition is de-coupled. We hypothesize that active perception alone, prior to any engagement of lateral inhibition feedback, can generate bistability of active/inhibited states. This crucially implies that in situations where single ECs experience intermediate levels of inhibition from their neighbors (common during collective decision making), bistability allows them to pre-commit to an activated or inhibited state. The subsequent lateral inhibition process is thus never called to amplify rapid random fluctuations in D difference between two neighbors. Rather, in each moment each single cell makes a clear decision, and presents its "vote" for lateral inhibition to amplify and lock in, speeding up coordinated decisions.

Bistability, hysteresis and positive feedback

The ability to dynamically select between two *distinct* phenotypes, while intermediate states are unstable, is a hallmark of bistable regulatory systems. In general, bistable systems can maintain two distinct locally stable states in a *single* environment. A simple mechanical analogy is that of a ball found on a double-well landscape (Fig. 3a). In this case, the physical shape of the landscape supporting the ball against gravity creates two stable states, i.e., the bottom of each well.

In the presence of any noise able to overcome friction between ball and surface, this mechanical system will not linger in an intermediate state, at the top of the barrier or between valleys. Positing an iron ball and an external magnet, it is also easy to appreciate that under certain environmental conditions (e.g. magnet on the right side of double-well) this system may be rendered mono-stable. Transitions between the two locally stable states take place abruptly, whenever forces on the ball exceed the potential barrier imposed by the presence of gravity. Moreover, slowly tuning the environment by moving the magnet position left to right and back again (such that the ball is restricted to the left / right / left valleys) uncovers a signature behavior of bistable systems, namely hysteresis (Fig. 3b). Charting the position of the ball as a function of the position of the magnet clearly reveals the initial-condition dependence of the ball's response. For any position of the magnet within a window around the barrier, the ball can settle into either of the two valleys, but which one depends on its recent history of positions. It cannot be stable in the transition state on top of the barrier, it will fall into one

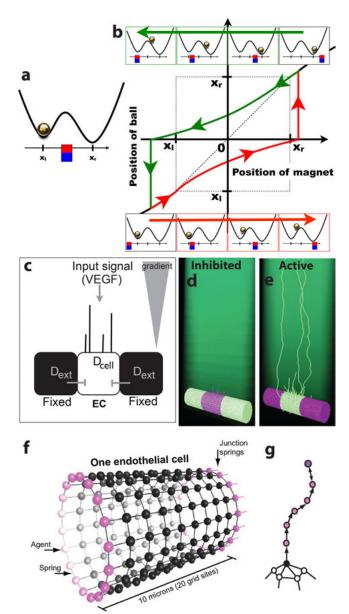

Figure 3. a) A mechanical bistable system - metal ball in a gravitational double-well potential. b) Moving a strong magnet under the ball acts as environmental input, capable of restricting the ball into a single well. As the magnet is slowly shifted from left to right (x-axis), the ball's position (y-axis) first changes slowly (bottom row; red), then undergoes an abrupt jump as the ball clears the barrier. Reverse arm: top row, green. In a wide region of magnetpositions, the ball's dynamics are bistable: it can reside in either valley depending on its initial conditions. c) The APB model setup, we track a single EC's activity (D_{cell}) as it responds to I in the environment and D_{ext} from its fixed neighbor cells. d-e) Frames at t= 300 from APB simulations, D levels high to low shown light green to purple, I gradient in environment shown dark green. d) A run where fixed neighbors have $D_{\text{ext}} = 10000 \, (D_{\text{max}})$ the central EC becomes inhibited (few short filopodia and low D_{cell}). e) A run where $D_{\rm ext} = 0$, the EC becomes active, $D_{\rm cell}$ is high and it has lots of long filopodia. f) The memAgent Model of an EC, reproduced from (Bentley et al 2009). The cell membrane is represented by a

cylindrical, single layer square lattice mesh of agents "memAgents", connected by springs. At either end (adjacent cells not shown) specialized junction springs and agents (pink) connect the cell to its neighbor cells along the vessel. g) To grow a filopodium new memAgents and springs are created.

of the valleys.

How can active perception endow ECs with such bistability? In regulatory circuits, bistability usually arises due to positive feedback (Angeli et.al., 2004; Cherry and Adler, 2000; Gardner et al., 2000; Ferrell, 2002). Active perception through filopodia and cell shape changes that extend the sensors to areas with high levels of input signal generate a potent regulatory drive for further filopodia extension (Fig. 2c). We therefore hypothesize that at intermediate levels of lateral inhibition by neighbors (when collective decisions are still in process) filopodia extensions are difficult enough to initiate that an inhibited state is locally stable. At the same time, should the cell already possess a large number of filopodia extended into a steep input gradient, these send enough signal back to stabilize and maintain an active moving state (Fig. 3g).

The Active Perception Bistability (APB) Model

To test our hypothesis, we developed a new simulation testbed that parallels the above mechanical example. We focus on how an individual cell's state changes as it experiences different, controlled levels of inhibition from two immobilized neighbor cells. Lateral inhibition from these two neighbors ("External D" or $D_{\rm ext}$) affects the individual EC under investigation (its current D level, " $D_{\rm cell}$ ", is used as proxy for its active/inhibited state), but these neighbors are uncoupled from being inhibited themselves (Fig 3c). $D_{\rm cell}$ is therefore analogous to the "ball" in the mechanical example of a bistable system and the fixed neighbors to the magnet; raising $D_{\rm ext}$ can push the cell into a more inhibited (low $D_{\rm cell}$) state and vice versa (Fig. 3d,e).

To simulate this scenario we use the memAgent Spring model (MSM model), which has been previously calibrated to experimental angiogenesis data – for full methods see Bentley et al (2008, 2009). Briefly, in this model cell morphology is represented as a surface comprised of many small agents (membrane agents, "memAgents") connected by springs following Hooke's law (which confer tension to the changing cell shape, akin to the actin cortex beneath a cells membrane) (Fig. 3f). The cell is 10 microns wide with 6 microns diameter (matching in vivo capillary dimensions). The world around it has dimensions (x,y,z=30,58,10 microns). The memAgents move in continuous space, but are snapped to a gridded lattice to implement local rules (grid sites represent $0.5 \times 0.5 \times 0.5$ micron cubes of space).

At each time-step an equal number of the cell's current, total sensors (S_{cell}) are distributed equally to each memAgent (S_{m}) over the cell's current surface shape. Dll4 ligands (D) are equally distributed to any memAgent in Moore neighborhoods of memAgents from other cells (on the interface between cells or "junctions"). The input signal (I) is modeled as a fixed linear gradient, where each grid site G above the vessel has I_G

level, calculated as $I_G = Vy$ where y is the y axis coordinate position of G and V is a tunable constant.

Signaling: Simplifying the description of the competitive receptor biology between different VEGFRs in the original MSM model, as it is not the direct focus of this study, we can state that the number of active sensors of a given memAgent m is calculated as $S'_m = S \cdot \sum I_G$. Notch is activated in each memAgent (resulting in the local removal of D from neighboring cell's memAgents), up to the value of N_m . If D < N then $N'_m = D$; if D > N, then $N' = N_{\text{max}}$.

Filopodia: memAgents extend filopodia by one grid site length at a time by creating non-branched chains of new memAgents adhered to the environment (fixed position) (Fig. 3g). These events are stochastic, with probability:

$$P(\text{extend filopodia}) = F \cdot S',$$

where F is a tunable constant. For full rules behind the actin dynamics, springs and enforcing the chain extension see Bentley et al (2009). Filopodia retract if the memAgent at the top of the chain has not extended for 10 time steps, which is more likely when sensors do not activate. They retract by iteratively snapping the chain of springs back to the next memAgent in the chain, whilst deleting memAgents as they go (based on in vitro observations). The cells have no limit on the length of a single filopodium, or how many they can initiate. However, their total length cannot exceed the total amount of actin available to the cell. The original model in Bentley et al (2009) generates full cell migration by releasing filopodia adhesions and allowing the springs to pull the cell forward. Here, however we keep adhesions fixed to control variables and ask whether shape changes due to filopodia alone can generate bistability.

Genetic Regulation: Briefly, the lateral inhibition is implemented each time step as follows:

$$S_{\text{cell}} = S_{\text{max}} - \sigma N''_{\text{cell}}$$

 $D_{\text{cell}} = D_{\text{cell}} + \delta S''_{\text{cell}}$

where σ , δ are constants and S'' denotes S' after a time delay (28 time steps) corresponding to the time it takes for transcription to alter gene expression in the nucleus, and subsequently protein levels at the cell surface. The new S_{cell} and D_{cell} levels are then redistributed to the memAgents and the process repeats on the next timestep.

Parameterization: All parameters in the model are set as in Bentley et al (2009), which were previously calibrated to experimental data. To investigate active perception we focus here on simulations varying its critical determinants: filopodia extension (F) and the input signal gradient (V). For normal EC behavior F = 2 and V = 0.04.

Results

Hysteresis simulations

We start with D_{ext} set to zero and thus simulate a fully active EC with long filopodia (Fig. 3e). We then slowly raise

the $D_{\rm ext}$ in increments of 50 until full inhibition is achieved, then reverse the process until it is yet again relieved. If active perception indeed creates bistability, we expect the transition between active/inhibited states to take place abruptly, at a $D_{\rm ext}$ threshold that is higher for the active \rightarrow inhibited transition than the reverse. In order to approximate quasi-static equilibrium while changing $D_{\rm ext}$, we tested the stability of $D_{\rm cell}$

levels using the following method: 1) we allowed a transient time window (250 time-steps) to pass, 2) we calculated the average and standard deviation of D_{cell} in two adjacent, non-overlapping sliding windows of size 250, 3) we tested whether $|\mu_c - \mu_p|/(\mu_c + \mu_p) < \varepsilon$ and $|\sigma_c - \sigma_p|/(\sigma_c + \sigma_p) < \varepsilon$, where μ_c/μ_p denote the average D_{cell} and σ_c/σ_p its standard deviation in the last/previous window ($\varepsilon = 0.5$). If the EC does not pass the

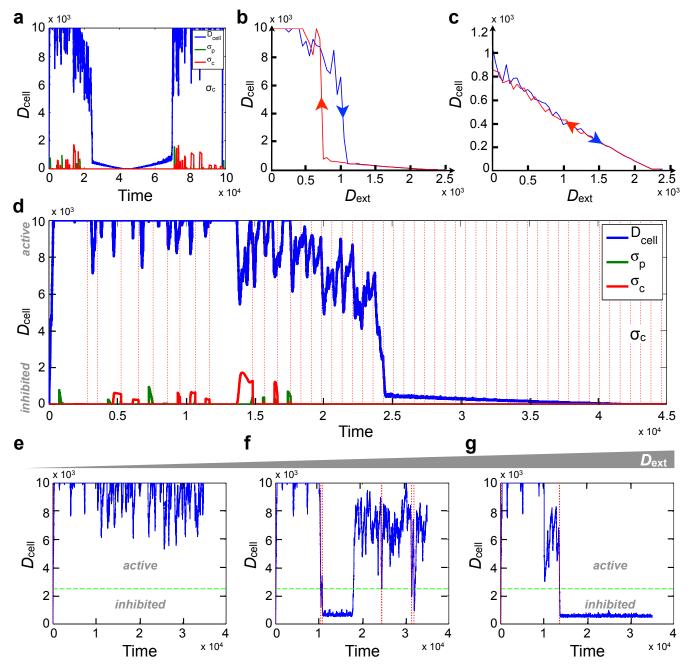

Figure 4. a) Time course of D_{cell} during a full cycle of hysteresis (blue). Standard deviation of D_{cell} , measured in two non-overlapping, expanding windows (σ_p for previous and σ_c for current windows) are shown in green and red, respectively. b) Hysteresis in the active / inhibited transitions of a single EC exposed to slowly increasing (blue), then decreasing (red) D_{ext} . c) Loss of hysteresis in a single EC with weak filipodia extensions, due to reduced sensorimotor feedback. d) Zoomed-in time course of D_{cell} during a half-cycle of hysteresis, showing large D_{cell} fluctuations in the active state. Red lines: times of D_{ext} increment. e-g) Long D_{cell} time-courses of ECs exposed to fixed D_{ext} . Green line: rarest observed D_{cell} value, marking the position of the barrier. Red line: transitions between active/inhibited states. e) $D_{\text{ext}} = 500$; EC restricted to the active state. f) $D_{\text{ext}} = 850$; bistable EC stochastically transitioning between active and inhibited states. g) $D_{\text{ext}} = 950$; EC restricted to its inhibited state.

test or a maximum time limit 60,000 was not yet reached, we increment the window. Otherwise we move on to the next $D_{\rm ext}$. Figure 4a shows the time-dependent evolution of $D_{\rm cell}$ through a full hysteresis cycle, along with its standard deviation measured in each window. As Figure 4b indicates, the system shows hysteresis behavior: as $D_{\rm ext}$ increases (blue arm of hysteresis curve), the cell goes through an abrupt transition from active (high $D_{\rm cell}$) to an inhibited state. Slowly decreasing $D_{\rm ext}$ (red arm) also leads to an abrupt transition from inhibited to active state, but $D_{\rm ext}$ needs to be lowered below the point at which the initial inhibition occurred. This indicates that there is a region of $D_{\rm ext}$ where the EC can exist in either its active or inhibited state, depending on its history.

To prove that active perception is required for this bistability, we repeated the simulations decreasing the rate of filopodia extensions (F) to half their normal value. When the filopodia-dependent sensorimotor feedback is thus weakened, the EC looses its bistability and becomes tunable, in that D_{cell} decreases proportionally with D_{ext} (Fig. 4c).

Due to the stochastic nature of filopodia extensions, D_{cell} fluctuations close to the bistable region are large (Fig. 4d; this is the rationale for the generous ε threshold of 0.5). Due to this inherent stochasticity, the exact D_{ext} thresholds at which abrupt transitions occur are not the same from simulation to simulation. Moreover, if the time window between increments is very large (well above the biological time scales involved in patterning), the EC may undergo stochastic transitions between metastable active/inhibited states. To understand the nature of these transitions, we set up a second set of simulations. In this case, we started the EC with $D_{\text{ext}} = 0$ and ran the simulation for 10^4 time steps, after which we abruptly increased D_{ext} to a nonzero target value, and performed $3 \cdot 10^4$

more steps. Figure 4e indicates that exposure to low $D_{\rm ext}$ (500) keeps the EC in an active state, albeit with sizable $D_{\rm cell}$ fluctuations. At the intermediate $D_{\rm ext}$ level of 850, however, the long simulation showcases abrupt, stochastic transitions between active and inhibited states (Fig. 4f). Lastly, high $D_{\rm ext}$ (950) causes a one-way transition from active to a strongly inhibited state (Fig. 4g). Even here, the transition is not immediate (\sim 0.3·10⁴ steps), but it is irreversible within the time window of the run.

To understand the dependence of the ECs residence time in each state, we partitioned D_{cell} values into active and inhibited

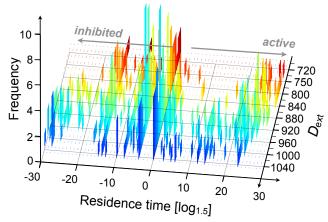

Figure 5. Distribution of residence times in the active and inhibited state (indicated by positive and negative x-values, respectively) in the course of long simulations in the presence of constant $D_{\rm ext}$ (red:low to blue: high). As $D_{\rm ext}$ increases, long residence times in the inhibited state gradually appear, while residence in the active state shortens.

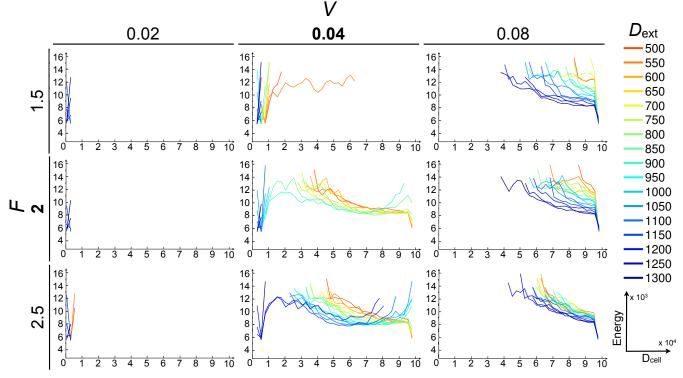

Figure 6. Free energy landscapes of the EC in the presence of constant D_{ext} , ranging from 550 (red) to 1300 (dark blue), as a function of V and F. Energy on the y-axis is calculated as $E = -\log[p(D_{\text{cell}})]$. Bold V/F values (middle panel) mark the control (biologically calibrated) case.

by choosing 2250 as the threshold of transition from Fig. 4d, and measured the length of uninterrupted residence times in each state. Their distribution as a function of $D_{\rm ext}$ is shown in Fig. 5. As expected, an increase in $D_{\rm ext}$ leads to the appearance of long residence in the inhibited state. In the $D_{\rm ext}$ range of 700-1040, the EC is not easily stuck in either state, and often performs rapid back-and forth jumps across the barrier. These rapid jumps are most like in the middle of this $D_{\rm ext}$ window, where long residence in both active and inhibited states are equally likely.

Energy Landscapes

In addition to residence times, long simulations under constant $D_{\rm ext}$ also allow us to map the "free energy landscape" of the EC in different conditions. To this end, we binned the $D_{\rm cell}$ range (B=250), measured the number of nonconsecutive time-steps the EC has $D_{\rm cell}$ in each bin $[n(D_{\rm cell})]$ and calculated the probability distribution

$$p(D_{\text{cell}}) = n(D_{\text{cell}}) / (B \cdot n_{\text{max}})$$

for each target $D_{\rm ext}$ ($n_{\rm max}$ is the total number of time-steps). The free energy of the EC is then proportional to $-\log(p)$. As expected, for intermediate $D_{\rm ext}$ values the energy landscape has two robust local minima (Fig. 6, control case: F=2; V=0.04). We tested the effect of altering active perception on the energy landscape. We find that a double-well energy landscape (and bistability) requires a balance between F and V. For example, altering V has a profound effect within the analyzed range of $D_{\rm ext} \in [550, 1300]$ (values that bracket the range of bistability for the control case). Weak / strong V completely destabilizes the active/inhibited state for this $D_{\rm ext}$ range, and renders the EC monostable. On the other hand F can only destabilize the active state when it is weak. Strong F results in a deeper potential well for the active state, without destabilizing the inhibited valley.

Collective patterning is temporally determined by active perception

So far we have focused on a single EC between fixed neighbors. However, if we have two ECs armed with active perception, they can form individual bistable switches, while D-N lateral inhibition between them guarantees that only one of them can exist in an active state at one time. This circuit design thus guarantees that two neighboring ECs form a higher-level bistable switch. In the setting of a multi-cell collective and in the presence of the input gradient they readily generate the S&P pattern (Fig 7a). In the single cell case, when F is reduced, or V is altered, the active perception and therefore bistability of the cells is weakened. This slows down the collective allocation of heterogeneous migratory phenotype (Fig 7b,c).

Discussion

This study represents a first step towards a new understanding of how coordinated movement decisions in heterogeneous collectives can be made efficient and robust. This paper presents the establishment of a new testbed, the APB model, and validation that the central hypothesis "active perception generates bistability" can be accepted. Hence

active perception and the move and decide perspective provide a novel explanation as to how heterogeneous states are so rapidly and robustly assigned in the collective morphogenesis of blood vessel growth. The bistability of single ECs faced with the intermediate levels of inhibition, typical of unpatterned phases, guarantees that state changes occur abruptly (rapid). Moreover, bistability confers shortterm memory to EC states in the face of small fluctuations (robustness). The sensitivity of angiogenesis to VEGF gradient and concentration changes in disease can now be viewed as an active perception defect. Overall, this study provides novel biological predictions, to be tested in vitro. How full cell movement, collective rearrangement and other signaling pathways feed back and interplay with active perception and collective bistability remains to be investigated in futures studies.

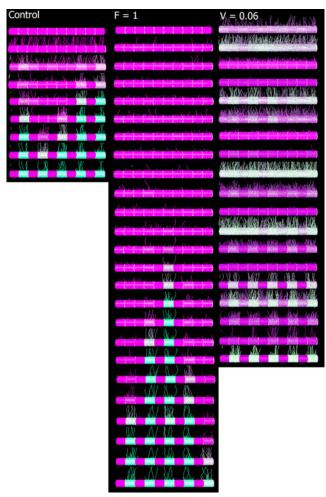

Figure 7. Time-space plots showing simulations with ten cells, periodic boundary conditions and lateral inhibition coupling. Frames every 100 time-steps shown vertically (Dll4 level high-low shown green-purple). It takes approx. 700t to reach the S&P pattern in normal conditions (Control, left panel). Halving the probability of filopodia (F=1, middle panel) slows down the collective patterning by over three times Control. Increasing the input signal (V=0.06, right panel) also slows down collective patterning, but this time due to the cell's synchronously oscillating whilst deciding, as the excessive input causes delayed excessive inhibition.

The reason for the positional interchanges during vascular morphogenesis is not yet known, though the dynamic and plastic nature of the cell phenotypes likely contributes to the adaptive capability of the collective network. This suggests that constant re-allocation of agent behaviors in heterogeneous collective systems via dynamic coordination, such as the active-perception-lateral-inhibition mechanism here, may also confer greater adaptability and robustness to collective robotics. Examples include systems where group plasticity facilitates role coordination, temporary scaffolds, and collective construction (Petersen et al 2011). Thus further study could also reveal important insights for morphogenic engineering principles.

Abstract

Inferring the social structures of animal groups from their observed behavior is a non-trivial task usually handled by direct observation. Recent advances in sensing and tracking technology have enabled the collection of dense spatial data over long periods of time automatically. The qualitative differences between sparse hand-coded data and dense tracking data necessitate a new approach to inferring the social structure of the observed animals. We present a framework for using agent-based simulations to guide our approach to inferring social structure from tracking data collected from a small group of rhesus macaques over a period of three months. As part of this framework, we describe a version of the DOM-WORLD model of dominance interactions in rhesus macaques that has been modified to include association preference, and adapted to more closely match the environment where the monkeys were housed. An exploration of simulation results reveals important characteristics of the tracking data. The inferred social structures of the tracked monkeys are also presented.

Introduction

Biologists and psychologists studying the social structures and dynamics of animals have relied on observation by trained researchers for the collection and coding of data, as until recently automated tracking systems have not been able to provide the accuracy required to recognize events of importance. With the advent of new tracking methods and subsequent improvements in tracking accuracy, it is now possible to record accurate, high-frequency spatial information over long periods of time. This qualitatively different kind of data requires a new approach to analysis.

As the sheer volume of data prohibits manual analysis, automated methods are necessary both for identifying key events and inferring relevant characteristics from identified events. In the rest of this paper, we examine how such automated methods can be applied in the specific case of inferring the social structure of a group of six rhesus macaque monkeys given tracking data of their movements over a period of three months at a rate of about 30Hz. In the next section we will review some related literature on social structure and agent-based modeling. Following that we will highlight

the specific aspects of social structure we are interested in recovering, and related behaviors. Next, we lay out our motivation for using agent-based modeling in this work. After that we cover the details of our approach to modeling, and inferring social structure. After that we present some results using simulated and real data. Finally, we provide some high level analysis, conclusions, and directions for future work.

Motivation and Related Work

Social structure in primate groups plays an important role in the health, behavior, and development of group members. Wallen (1996) has shown that social structure plays an important role in the development of behavioral sex differences, while Stephens and Wallen (2013) describe how social status can effect the actual physiological development of young monkeys. Sapolsky (2005) reviews how social status can effect a wide range of health issues, both direct (such as access to resources), and indirect (stress related diseases). Being able to automatically infer the social structure of a group of animals then has wide ranging implications from maintaining the health and safety of laboratory animals, to determining the changes in social structure throughout the course of an experimental protocol.

In order to guide our development of automatic algorithms for inferring social structures from dense tracking data, we take an agent-based modeling approach to creating simulations of animal behavior in order to prototype and refine our methods. The work presented by Yang et al. (2012) has a similar goal, and provides a principled framework for using agent-based models to further the ethological study of foraging behaviors, specifically the foraging behavior of Aphaenogaster cockerelli. Hrolenok and Balch (2013a) presented work on learning these agent-based models of ant foraging directly from data using techniques from machine learning, and later (2013b) fish schooling, although there the purpose was the automated learning of the behavior model itself, while in this work we are interested in developing inference techniques using a known model. Our development of this known model is heavily influenced by DOMWORLD, introduced by Hemelrijk (2000). Hemelrijk

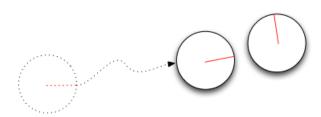

Figure 1: An approaching behavior that indicates an association preference. The strength of the indicated association preference is determined by the frequency and length of periods of close proximity.

presents an agent-based model of dominance in primates that emerges spatial patterns typically found among certain types of rhesus macaque troops.

Social Structures in Rhesus Macaques

One of the most intuitive measures of social structure in primates is association preference, which indicates which members of the group each individual prefers to spend time in close proximity to. A graph constructed from association preferences can illuminate subgroups, key individuals which connect otherwise disconnected groups (also known as cut vertices, or articulation points), as well as overall measures of group structure such as connectedness. The observable behavior where two or more monkeys spend time within relatively close proximity to one another indicates association preference. Figure 1 illustrates a grouping behavior that indicates association.

Another important measure of social structure is the dominance hierarchy. Dominance plays important roles both in interactions between individuals and group dynamics, and changes in dominance can indicate significant events of interest to the primate researcher. Observed displacement and withdrawing behaviors such as chasing and fleeing indicate a dominance relationship. Figure 2 illustrates a withdrawal behavior that indicates a dominance relationship.

While some association, displacement, or withdrawing behaviors can only be identified visually, a large number of them can be detected directly from spatial data, as described in later sections. In order to obtain this data, we utilized a 3D position tracking system to track the positions of 6 monkeys in a 3m x 3m enclosure over a period of three months. Details of the tracking system are described in Huang et al. (2012).

The Importance of Agent Based Models

Agent-based modeling and simulation of animals solve two major problems in the experimental study of animal behavior. First, the data collection cost associated with studies

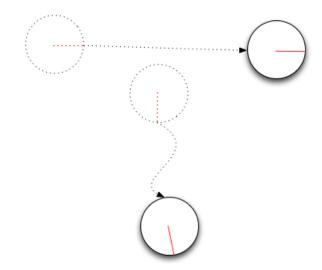

Figure 2: A withdrawal behavior that indicates an dominance relationship. The strength of the indicated dominance relationship is determined by the relative frequency with which each individual withdraws from the other.

done in simulation using high fidelity models is essentially zero, at least compared to the cost of running experiments and collecting data on real animal subjects. Using ABMs allows the researcher to run simulated experiments to increase the confidence of statistical analysis which might otherwise be less conclusive.

Second, when inferring model parameters directly from data, one is faced with the task of validation without access to any "ground truth". Performing the same inference methods on simulated data can provide crucial insight into how those techniques may perform on data from live animals. Both success and failure can be valuable clues into the capabilities and limitations of the inference methods.

In this work, we focus on using ABMs as a validation tool. In the next section we introduce an agent-based model of social interactions between monkeys based on a well studied simulation with slight modifications relevant to the specific social measures mentioned previously. Using this ABM, we can measure quantitatively the effectiveness of our methods for recovering social structure.

Methodology

To validate our method for inferring social structure, we created an agent-based model that incorporates the important behaviors mentioned previously, parameterized in a way that allowed us to compare the recovered social structures with the "ground truth" of the simulation.

Agent Based Behavior Model

Our simulation model, which we call SMALLDOMWORLD is a modification of the earlier DOMWORLD of Hemelrijk

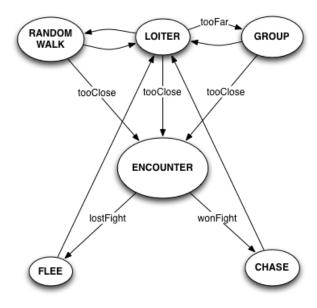

Figure 3: The SMALLDOMWORLD model.

(2000). The behavior of the individuals is guided by three components: a grouping component that draws individuals together, a dominance component where individuals confront each other and the winner chases the loser, and a random component where individuals wander about their environment at low speed.

In order to match the environmental conditions of the animals being studied, we modified the DOMWORLD model presented in Hemelrijk (2000) in a number of ways. In the troop we studied, the dominance relationships were already stable and established, where as in DOMWORLD, dominance relationships are recalculated after every encounter. In DOMWORLD, as in our model, dominance encounters only occur when an individual approaches another within some distance threshold representing an intrusion into personal space. In our model, the probability of an intrusion on personal space resulting in a dominance encounter is given by the parameter σ where $\sigma = 1.0$ indicates a completely stable dominance structure with no confrontations, and $\sigma = 0.0$ ensures that any intrusion results in a confrontation. We use the same dominance confrontation mechanism as DOM-WORLD: each individual is given a dominance weight, and the difference in weights probabilistically determines the winner of any encounter (see Hemelrijk (2000) for details).

We also introduced some selectivity into the grouping behavior. Grouping in DOMWORLD represented a desire by all individuals in the group to remain within some proximity of other group members, and so when an individual found itself far away from the center of the group, it selected another visible member of the group uniformly randomly to head to-

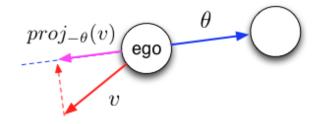

Figure 4: Detection of fleeing events.

wards. In our model, each individual has a list of association preferences $\pi = \langle \pi_1, \pi_2, \dots, \pi_n \rangle$ which can be thought of as the distribution over individuals selected for grouping. This leads to patterns of association which are non-uniform and give rise to the social structures described earlier. The list of association preferences can be combined into a single association preference matrix P with each row corresponding to a single individual's association preferences.

While these two modifications represent the most important changes between our model and DOMWORLD, we also made several changes to accommodate differences in the modeled environment and simulation engine. DOMWORLD's environment is long-range, discrete, and unbounded (toroidal in implementation), whereas our environment is quite small, continuous, and interactions with the boundary of the enclosure are common (which necessitated some kind of obstacle avoidance behaviors). Figure 3 gives a graphical representation of the behavior model of individuals in SMALLDOMWORLD.

Heuristic Behavior Recognition

In this section we present two heuristic methods for identifying association and dominance behaviors, and how they can be used to infer the social structures of a group of monkeys.

Time spent within proximity is a straightforward way to detect behavior which indicates association preference among group members. By counting the frequency and length of events where the ego — by which we mean the individual whose preferences we are trying to determine — comes within a threshold distance of another individual, and remains there at low to zero velocity for at least some minimum period of time, we can infer which individuals the ego prefers to spend time with. If we denote by E_{ij} the time monkeys i and j spend near each other, then we can fill out the entries of the association preference matrix P as:

$$P_{ij} = \frac{E_{ij}}{\sum_{k} E_{ik}} \tag{1}$$

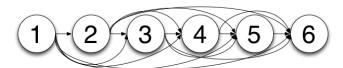

Figure 6: Dominance hierarchy.

While detecting all types of withdrawal events may be difficult, we can capture a certain subset fairly easily. One type of withdrawal involves the ego rapid moving directly away from the target, which we will call *fleeing* events. We can detect fleeing events by counting the length and number of events where the magnitude of the ego's velocity (v) projected onto the bearing (θ) between the ego and target is larger than a threshold (f), which is shown graphically in Figure 4. For each pair of individuals we can compute a dominance measure d as

$$d_{AB} = \left| \left\{ e_{AB} \mid proj_{-\theta(A,B)}(v_B) > f \right\} \right| \tag{2}$$

If individual A flees from individual B more frequently than the opposite $(d_{BA} > d_{AB})$, we can infer that A is subordinate to B. In practice, picking f to correspond to roughly 30 degrees on either side of moving directly away from the target worked well.

Experiments

We performed four experiments to test our approach, three using data collected from our simulation model SMALL-DOMWORLD with different parameterizations of the social structure, and one using the three months of tracking data we collected from a small group of animals. Our purpose in performing the simulation experiments was to measure how accurately we would be able to recover social structure, and to characterize scenarios where our method might not be able to recover social structure. In each of the simulation experiments we ran ten experiments under the same parameterization but with different initial configurations and random seeds.

In the first experiment, we simulated a group of monkeys which had a social structure with two disconnected subgroups, as shown in Figure 5. The parameterization which realized this structure had each individual's association preference set to 1.0 for other members of its subgroup, and 0.0 otherwise. This way there should be no deliberate preference to spend time in proximity of non-subgroup members. The dominance relationships for this and the two following simulation experiments was a direct linear relationship with rank corresponding to ID, as illustrated in Figure 6. The parameterization that realized this model set the dominance weight for the least dominant individual to 1.0, with each individual higher in the chain having twice the dominance

Table 1: Simulation parameters common for all experiments.

Personal distance	0.25m
Near distance	0.8m
Fleeing speed	2.0m/s
Chasing speed	1.0m/s
Grouping speed	0.25m/s
Wander speed	0.12m/s

Table 2: Frobenious error of recovered association preference as compared to a randomly generated symmetric, normalized matrix with zero diagonal. Averaged over 10 runs.

Recovered AP	Avg. error (std.)	random AP	
disconnected	0.1744 (0.0014)	0.2408 (0.0326)	
neutral hinge	0.1002 (0.0015)	0.1797 (0.0350)	
preferred hinge	0.1388 (0.0004)	0.1869 (0.0158)	

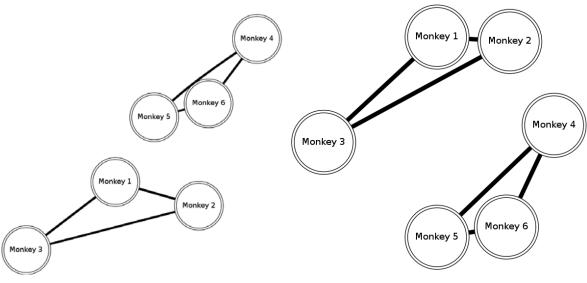

weight as the next lowest, or $(D=2^{N-i})$. The same dominance weights were used in each experiment. Hierarchy stability was set fairly high $(\sigma=0.8)$, so that dominance interactions were not frequent, but still frequent enough to reliably detect the dominance hierarchy. Other simulation parameters are listed in Table 1 and were estimated from tracking data of live monkeys where appropriate, or taken from the literature when available.

We were successfully able to consistently recover both the dominance relationships and association preferences in this experiment. In order to get a sense of our accuracy, we compared the recovered association preference matrix with the ground truth parameterization and with a randomly generated matrix which was restricted to the same form (rownormalized, zero-diagonal, symmetric). The results of this comparison are given in the first row of Table 2, which shows that our recovered parameters are significantly closer to the ground truth than random. In order to recover the graph structure shown in Figure 5, we chose a threshold τ , such that edges larger than τ are included in the graph while those smaller are not. In order to characterize our ability to pick τ reliably, we examined the distribution of values in the association preference matrix P, shown in Figure 7. The distribution is clearly divided into two modes, which indicates that by picking a a threshold between the two modes, our recovered graph will be stable to noise in the estimation of association preferences. In our testing, picking

$$\tau = \frac{1}{n^2} \sum_{i,j} P_{ij} \tag{3}$$

where n is the number of agents, worked reliably.

In the second experiment, we modified the association preferences so that one individual, which we will call the

(a) Recovered association preference.

(b) Ground truth association preference.

Figure 5: Association preferences for the disconnected scenario. The recovered graph (5a) closely matches the actual association preferences used in the simulation (5b). Line thickness corresponds to strength of association preference. Association preferences that fall below the threshold τ (from Equation 3) are not shown.

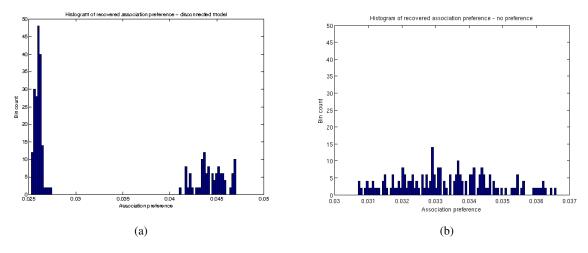

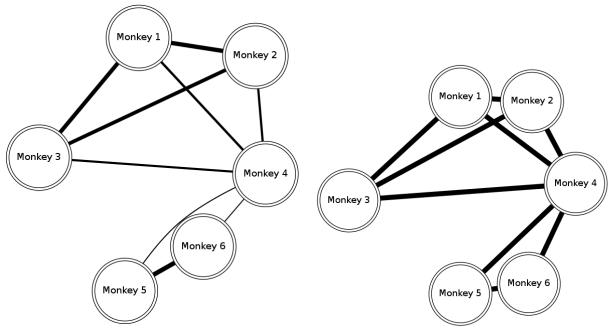

Figure 7: Histogram of association preference values recovered (7a) from the disconnected scenario, and (7b) a simulation with no association preferences. In the second simulation, agents followed the same behavior model, except when choosing to group where they chose among neighbors without preference. Notice the clear separation into two modes of the recovered association preferences as compared to the noisy unimodal distribution from the simulation with no preferences.

(a) Recovered association preference.

(b) Ground truth association preference.

Figure 8: Association preferences with hinge node. The recovered graph (8a) closely matches the actual association preferences used in the simulation (8b). Line thickness corresponds to strength of association preference. Association preferences that fall below the threshold τ are not shown.

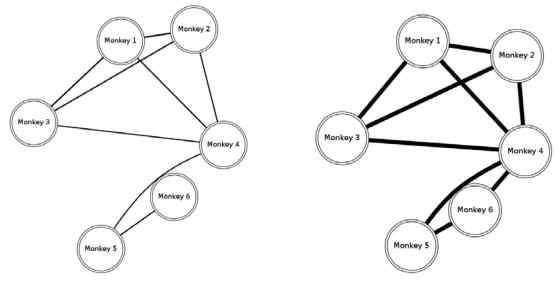

hinge, became an articulation point linking the two subgroups, as shown in Figure 8. To do this, we modified the association parameters such that the hinge individual preferred everyone equally, but no one had a preference for them. In terms of our parameterization, we set the hinge individual's row $P_{hj}=1.0, \forall j,$ and its column $P_{ih}=0.0, \forall i.$ Results are shown in the second row of Figure 2. Again, the recovered association preference is significantly closer to the ground truth than a random association preference, and the dominance hierarchy was recovered without error.

In the third experiment, we repeated the previous experiment, but also allowed the other individuals to preferentially group with the hinge individual by setting $P_{ih} = 1.0, \forall i$. By doing this we highlight a potential scenario where our method may not be able to recover the social structure accurately, specifically non-transitive association preferences. Note that our metric for association preference makes no distinction between individuals which are within proximity because they chose to be, and those that just happen to be nearby. For example, if individuals A and B do not have any preference for association, but each has a high preference for associating with a third party C, then regardless of C's preferences, A and B will spend a high proportion of time in proximity of one another. Figure 9 as well as the third row of Figure 2 illustrate how recovery performance is degraded in this type of non-transitive scenario.

Finally, for our fourth experiment we applied our methods to tracking data of live animals. Figures 10 and 11 show the recovered association preferences and dominance hierarchy for the entire period the monkeys were tracked. We picked τ using the same approach described above, although from examining the distribution of association preferences shown in Figure 12, we know that this choice will be less stable with respect to noise. That is, it is more likely that some edges will be included or excluded from the graph due to small changes in association preference. The dominance relationship is a linear hierarchy (4,3,5,2,6,1) with individual 4 being the most dominant, and individual 1 being the least dominant. This agrees with the recovered association preference, where individuals are shown as preferring to associate with other individuals at similar ranks in the hierarchy.

Conclusion

We have described a framework for using agent-based models to explore the characteristics of automated techniques for analyzing dense spatial data. In the specific case of inferring the social structure of rhesus macaques from tracking data, we have illustrated under what conditions simple heuristic analysis can provide accurate reconstructions of social structure, and provided some insight into the stability and reliability of our approach using an extension of the DOM-WORLD agent-based model to guide our analysis.

(a) Recovered association preference.

(b) Ground truth association preference.

Figure 9: Association preferences for the hinge node scenario using non-transitive preferences. The recovered graph (9a) is missing a link between monkey 6 and monkey 4 in the actual association preference graph (9b). Notice also that the magnitude of the preferences — shown by the thickness of the edges — is much closer to the threshold value τ . Picking smaller τ results in additional edges that are not present in the simulated behavior. The non-transitive preferences make it difficult to choose a stable τ .

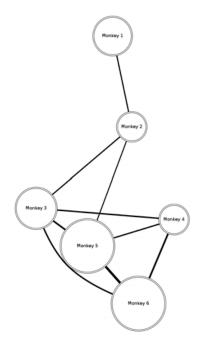

Figure 10: Association preferences for live animals. Diameter of the node is determined by the sum of association preferences for that node. Links are included if they are larger than the mean association preference, and their width is determined by how strong the association preference between the two nodes is.

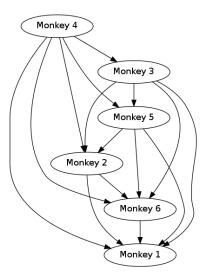

Figure 11: Dominance hierarchy for live animals. Linear chain hierarchies match with our simulated model of dominance behavior, but it is important to note that no part of our inference of dominance relationships *enforces* linear chains. So if the live animals had been an egalitarian troop with little to no aggressive displays, or if the dominance rankings had not been established, we would expect to see a different kind of dominance structure.

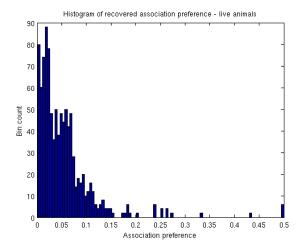

Figure 12: Histogram of association preference values recovered from the live animals. The secondary mode in this distribution is less distinct, but there still is a separation into low and high preference levels.

In future work we would like to expand our approach to include more sophisticated inference techniques. It may be the case that fairly simple probabilistic models will be able to capture some of the structure that we are not able to recover directly from observed behaviors. Association and dominance are clearly not independent relationships, and incorporating some notion of how each affects the other may allow us to improve the accuracy of our inference.

Evolution of Collective Behaviors by Minimizing Surprise

Heiko Hamann

Department of Computer Science, University of Paderborn, Germany heiko.hamann@uni-paderborn.de

Abstract

Similarly to evolving controllers for single robots also controllers for groups of robots can be generated by applying evolutionary algorithms. Usually a fitness function rewards desired behavioral features. Here we investigate an alternative method that generates collective behaviors almost only as a by-product. We roughly follow the idea of Helmholtz that perception is a process based on probabilistic inference and evolve an internal model that is supposed to predict the agent's future perceptions. Separated from this prediction model the agent also evolves a regular controller. Direct selective pressure, however, is only effective on the prediction model by minimizing prediction error (surprise). Our results show that a number of basic collective behaviors emerge by this approach, such as dispersion, aggregation, and flocking. The probability that a certain behavior emerges and also the difficulty of making correct predictions depends on the swarm density. The reported method has potential to be another simple approach to open-ended evolution analogical to the search for novelty.

Introduction

The creation of control algorithms for self-organizing, artificial collective systems is challenging because it is difficult to anticipate how a multitude of local interactions will effect the global behavior. Hence, evolutionary algorithms are a good option. A desired behavior is evolved by defining a fitness function that rewards the occurrence of particular behavioral features. Alternatively, an indirect selective pressure can be generated that does not directly influence the evolved behavior while interesting behaviors should still emerge. In this paper we investigate one of such alternatives by evolving an agent, that tries to predict its future perception, while a number of collective behaviors is obtained almost only as a by-product.

Evolution of collective behaviors

The application of swarm intelligence (Bonabeau et al., 1999) to the field of robotics is called swarm robotics (Dorigo and Şahin, 2004; Brambilla et al., 2013). The problem of designing algorithms for swarm robotics that generate the desired behaviors (swarm engineering,

Brambilla et al. (2013)) is challenging because it means to design self-organizing systems. Self-organization relies on feedback processes and a multitude of interactions (Bonabeau et al., 1999) that have effects which are difficult to anticipate. One solution is to develop global models that predict the expected collective behavior and give insights about underlying principles (Hamann, 2010; Martinoli et al., 2004). Another approach is to apply methods from evolutionary robotics (Nolfi and Floreano, 2000) to swarm robotics, that is, evolutionary swarm robotics (Trianni, 2008). For example, the evolution of an aggregation behavior in robot simulations (Trianni et al., 2003) and also the evolution of communication in combination with collective motion were reported (Trianni et al., 2004).

In evolutionary robotics the design of fitness functions is a challenging issue. For example, the unfavorable approach of defining elaborated complex fitness functions, that predefine many behavioral features of the expected behavior, is feasible. That way intrinsically complex robot tasks are simplified by exploiting a priori knowledge which foils the key idea of evolutionary robotics that it is a preferential approach whenever there is only little a priori knowledge (Nelson et al., 2009). Another issue of fitness functions is that the evolutionary algorithm might converge prematurely. To overcome these challenges, new approaches were reported, such as novelty search and related methods (Lehman and Stanley, 2008; Mouret and Doncieux, 2009). The successful application of novelty search to swarm robotics was recently reported (Gomes et al., 2013). Artificial life is a related field in this context, there the evolution of collective behaviors within artificial ecologies was reported that either rely on selective pressure generated by ecological features only (Schmickl and Crailsheim, 2006) or in combination with explicit fitness functions (Ward et al., 2001).

Behavior based on minimization of surprise

Many common approaches in the field of intelligent agents focus on defining condition-action rules or similar methods to generate intelligent behavior. In evolutionary robotics (Nolfi and Floreano, 2000) the common approach is based on reactive control possibly combined with simple internal states which means complex world models are usually not considered. That leaves a considerable gap to mammals but also to insects such as honeybees that have capabilities for learning and memory (Hammer and Menzel, 1995). An initial step towards the evolution of simple world models would prepare to go beyond the limited capabilities of reactive agents.

There are many theories that try to define a systemic concept of brains which would allow to explain the variety of behaviors we observe in animals. One of these theories goes back to von Helmholtz (1867) who argued that perception is a process based on probabilistic inference. According to that the main challenge imposed on each animal's brain is to determine coherent causes to its sensory inputs. This abstract concept was picked up, for example, in machine learning to solve the unsupervised learning task of creating a model for a given data set. The so-called Helmholtz machines (Dayan et al., 1995) are trained to serve as a generative model, that is, they learn a probabilistic model of an assumed hidden structure of the input data. Following this concept the brain can be understood as a 'prediction machine' that learns models which describe the causes of its perceptions. Furthermore, a plausible assumption to make is that minimizing the prediction error of this model is advantageous for the considered organism. This line of thought is implemented in a mathematical framework by Friston (2010) which defines an information-theoretic analogon to thermodynamic (Helmholtz) free energy. Basically he defines this free energy as the prediction error. This approach based on a 'freeenergy principle' has the potential to be a unified brain theory (Friston, 2010; Friston et al., 2006). The connection to Darwinian evolution is established by the argument that minimal prediction errors indirectly confine the set of stateaction pairs, that are experienced and executed by an agent, which in turn limits the living space and is life prolonging: "By sampling or navigating the environment selectively they restrict their exchange with it within bounds that preserve their physical integrity and allow them to last longer" (Friston et al., 2006). A minimal prediction error is hence interpreted as an evolutionary advantage. While Friston mostly focuses on simple agent–environment interactions, we apply this concept to agent-agent interactions in a collective system here. In the case of a swarm, the future perceptions of an agent not only depend on its own actions (and a possibly dynamic environment) but also on the actions of other close-by agents. This adds another feedback loop to Friston's framework that indirectly asks the prediction machine to predict other prediction machines. These prediction machines can be interpreted as world models as used in intelligent agents. However, they are not applied as a mere tool to make intelligent decisions but as the main driving force for the emergence of intelligent behavior.

Similar work is, for example, that of Capdepuy et al. (2007) which is based on an information-theoretic measure called 'empowerment'. Empowerment is the "maximum potential information an agent can transfer into its own sensors through the environment" (Capdepuy et al., 2007). The reported simulations are of large-scale (1000 agents) in a grid world and mostly aggregation phenomena are observed. Also the work of Oudeyer et al. (2007) is related which focuses, however, on single robot settings. They propose a sophisticated learning approach which tries to put the robot into situations that allow for a maximal learning progress. The derivative of the error rate curve of a learning machine is monitored and a classification system needs to be trained that structures the robot's sensory contexts. Furthermore note that making this connection between the neurosciences and swarm intelligence follows the idea of 'swarm cognition' (Trianni et al., 2010).

Basic collective behaviors

In general there is a big variety of collective behaviors including rather complex behaviors, such as foraging, sorting, nest building, and cooperative transport (Bonabeau et al., 1999). At the other end of the scale there are simple collective behaviors that are restricted to agent–agent interactions without explicit agent–environment interactions. These simple behaviors rely exclusively on agent positions and agent motion while not including environmental features. There are four basic collective behaviors that are based on motion (moving or stopped) and relative positions (minimal distances between agents or maximal distances) only. On the basis of these two dimensions they are categorized: dispersion (maximal distances, stopped), aggregation (minimal distances, stopped), random (maximal distances, moving), and flocking (minimal distances, moving).

In the following we focus on these four collective behaviors of low complexity and investigate the necessary conditions that allow them to emerge. Following the motivation of the free-energy principle, our objective is to provoke the emergence of these behaviors without an explicit external force acting on agent behaviors or agent controllers and also without explicit selective pressure due to ecological features such as ecological niches or co-evolution. The investigated hypothesis is that a mere selection for minimal surprise (i.e., minimal prediction error, minimal free energy, Friston (2010)) is sufficient to evolve these four simple collective behaviors. Note that a short overview of this research was published before (Hamann, 2014).

Model

Our swarm model is roughly inspired by the desert locust, *Schistocerca gregaria*, that shows collective motion (often called 'marching bands') in the growth stage of a wingless nymph (Buhl et al., 2006). Buhl et al. reduce the collective motion of the locusts to a quasi-one-dimensional sys-

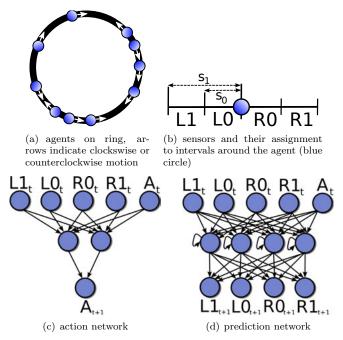

Figure 1: Experimental setting, sensor setting, and artificial neural networks for control and prediction.

tem in their experiments by placing the animals in a ringshaped arena. The observed directional alignment of a majority of locusts is density-dependent and individuals seem to change their direction as a response to neighbors. Here the agents move in 1-d space in the form of a circle, in the following called ring (see Fig. 1a). The ring's circumference is denoted by ring length L. The agents choose from only two available actions: moving clockwise or moving counterclockwise. However, the agents have no global reference frame, that is, whether they are moving clockwise or counterclockwise is unknown to them. Hence, they actually choose from two actions: staying with the current direction or switching the direction. They are not allowed to stop. The

parameter	value

elitism	1
mutation rate	0.05
ring length L (circumference)	[5, 50]

Table 1: Parameter settings.

agents have four sensors (L1,L0,R0,R1) that cover four intervals of their neighborhood defined by sensor distances s_0 and s_1 (see Fig. 1b and table 1 for the used parameters). The sensors are discrete and output either a '1' if there is at least one neighboring agent within the respective interval or a '0' if there is no agent.

In the following experiments the swarm size is fixed to N=20 agents while the ring length L is varied between experiments. This allows to test different swarm densities N/L. Initially the agents are positioned in space by sampling from a random uniform distribution and also their initial direction is chosen with equal probabilities. Time is discrete and each agent's position is updated by adding or subtracting the agent speed of v=0.1. In addition, a small noise is applied to the agent's position by adding a random uniform value sampled from [-0.01, 0.01]. This small noise was added to the system based on the heuristic experience that it triggers a bigger diversity of behaviors. The agents are allowed to pass each other without any interference.

Each agent is equipped with two independent artificial neural networks (ANN) that we call 'action network' and 'prediction network'. The action network has 5 input neurons, 2 hidden neurons, and 1 output neuron (see Fig. 1c). The inputs are the 4 sensor values (L1,L0,R0,R1) and the last action. That way the ANN is a recurrent network although it is implemented as a feedforward network. The output neuron determines the next action (stay with current direction or switch direction) based on a threshold. The prediction network has 5 input neurons, 4 hidden neurons, and 4 output neurons (see Fig. 1d). The input is the same as with the action network. Each hidden neuron has a self-loop which explicitly implements a recurrent network. The output of the prediction network are 4 values that are associated with the 4 intervals of the 4 sensors (L1,L0,R0,R1). Each output neuron determines the predicted value of the respective sensor for the next time step. The agent actually tries to predict where its neighbors will be positioned in the next time step.

We apply a simple evolutionary algorithm. The genomes consist of two sets of weights, one for the action network and one for the prediction network. Note that by applying an evolutionary algorithm we introduce a second concept of a population in this work which is the population of genomes (in difference to the population of agents that are run in the simulations). This population size is 50. Initially a population of random networks is generated (weights are random uniform over [-0.5, 0.5]). The genomes are evaluated by applying the above described swarm simulation. For a particular evaluation run all agents of the simulation share the same genetic material, that is, they have the same networks as defined by the genome that is currently evaluated. The fitness function rewards good predictions of the prediction

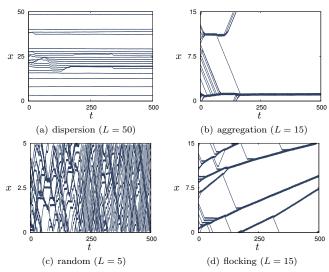

Figure 2: Trajectories of all agents for the four basic swarm behaviors: dispersion, aggregation, random, and flocking.

network. It is defined by

$$F = \frac{1}{NT} \sum_{t \in \{0,1,\dots,T-1\}} \sum_{i \in \{0,1,\dots,N-1\}} \sum_{j \in \{L1,L0,R0,R1\}} c_{i,j}(t)$$
(1)

whereas N is the swarm size, T is the length of the evaluation in time steps, and $c_{i,j}(t)=1$ if the prediction of the previous time step for sensor j of agent i matches the current value of sensor j, otherwise $c_{i,j}(t)=0$. For time t=0 the predictions are set to 0 by definition. The evaluation of a genome is averaged over the results from 10 independent simulation runs. The theoretical best fitness is 4. Note that the behavior of the agents as defined by the output of the action network is not a direct subject to the fitness function because only correct predictions of the prediction network are rewarded. Each weight of both the action network and the prediction network is mutated with a probability of 0.05. Proportionate selection and elitism of 1 are used. Evolution is run for 30 generations totaling to 1500 evaluations (each based on 10 independent runs of the simulator).

Results

All four of the above mentioned basic collective behaviors are found among the best evolved individuals over different swarm densities. Fig. 2 shows example trajectories of all N=20 agents for each of these behaviors (vertical axis gives position x of agents on the ring, horizontal axis gives evolution in time t). The agents cannot simply stop but by permanently switching between clockwise and counterclockwise motion (output of action network always 'switch') they cover no distance averaged over several steps as seen in Fig. 2a. Arguably this behavior can be called dispersion although the agents are initially positioned by sampling from a uniform distribution. Agents that

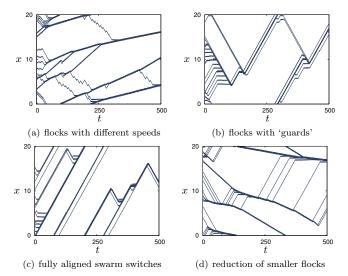

Figure 3: Trajectories of all agents for interesting collective behaviors (L=20).

are initially close-by actually increase the distance between them. Similarly in some runs the agents also manage to stay together in a cluster of high density after they have aggregated as seen in Fig. 2b. Another behavior is seen in Fig. 2c. By rarely switching the direction (output of action network mostly 'stay') the agents cover maximal distance and logically form two groups (clockwise and counterclockwise) distributed over the whole ring. If the agents aggregate but still cover some distance, then we get a flocking behavior as seen in Fig. 2d. Also note that these flocks manage to travel with different velocities (i.e., different cyclic combinations of clockwise/counterclockwise motion). Fig. 3 shows a few more examples of the obtained collective behaviors for a medium swarm density (L = 20) to document the variety of behaviors. Fig. 3a shows an example for flocks moving with different velocities depending on their size. All flocks have positive velocities and small flocks move faster. That way the small flocks catch up and join the bigger flocks. Fig. 3b shows a flock with one agent at each side virtually as 'guards'. Fig. 3c shows a fully aligned swarm that abruptly switches its direction (similarly to observations of locusts, see Buhl et al. (2006). Fig. 3d shows a technique to reduce the size of smaller flocks one by one to form a single flock.

Fitness of best evolved individuals

Next we investigate a series of experiments for varied ring lengths $L \in \{5, 10, 15, 20, 25, 30, 35, 40, 45, 50\}$. Varying the ring length means varying the swarm density because the swarm size is fixed to N=20. For each ring length L, 200 independent evolutionary runs were done. In the following the focus is on the best evolved individuals, that is, the best prediction machines. For the example of ring length L=25 the increase of the best fitness over generations is shown in Fig. 4a (reported before, Hamann (2014)).

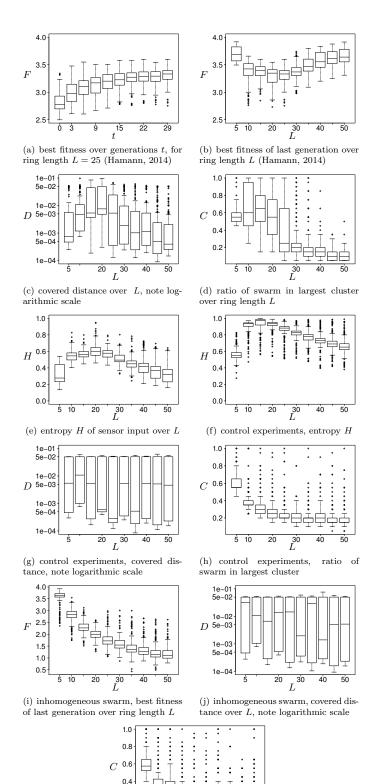

Figure 4: Results – fitness, cov. dist., largest cluster, entropy.

swarm in largest cluster over L

swarm,

ratio of

(k) inhomogeneous

After a fast increase for generations t < 15, a saturation in the best fitness is seen. The median of the last generation (t = 29) is 3.33 which means that the prediction network is predicting in average 83.3% of the sensor values correctly. In Fig. 4b a comparison of the last generation's best individual fitness is given for all settings of the ring length L(reported before, Hamann (2014)). The highest median best fitness is reached for L = 5 (3.68) and for L = 50(3.64) whereas the lowest median best fitness is obtained for L=25 (3.33). With increasing ring length (i.e., decreasing swarm density) the medians decrease (L < 30) and start to increase again for L > 25. From this result we infer that the prediction task is more difficult for medium density (10 $\leq L \leq$ 35) without excluding the possibility that better results could be achieved by investing more resources to the optimization process. For very high densities prediction seems easy because most of the time all sensors detect neighbors and hence the perception changes only infrequently. For very low densities prediction seems also easy because most of the time all sensors detect no neighbors. For medium densities, however, the detection of neighbors might change often hence always predicting the detection of neighbors or always predicting that no neighbors will be detected is insufficient.

Covered distance

In the following we investigate the evolved behaviors. This is done along the above mentioned two dimensions of basic collective behaviors, namely covered distance and distance between agents. The covered distance is measured over a period of time $\tau = \frac{L}{2v}$ at the end of the evaluation. It is the sum of all agents' covered distances. It is normalized by the length of the time period and the swarm size N. We get

$$D = \frac{1}{N\tau} \sum_{i \in \{0,1,\dots,N-1\}} |x_i(T-\tau) - x_i(T)|, \quad (2)$$

whereas $x_i(t)$ is the position of agent i at time t. The covered distance has a maximum of $D_{\rm max}=0.1=v$. In Fig. 4c the results averaged over the population of the last generation of the 200 independent evolutionary runs for varied ring length are given (note logarithmic scale). With increasing ring length (i.e., decreasing swarm density) the median covered distance increases (L<25) and starts to decrease again for L>20. Hence, it is very likely to see a static swarm for ring length L=50 and rather unlikely for L=20.

Largest cluster

As an indicator for the distances between agents we determine the largest cluster. For each agent we determine the total number of agents within a distance of s_1 (i.e., we count all agents that are in any of the four intervals of sensors L1, L0, R0, R1). The maximum over these numbers divided by swarm size N determines the size C of the largest cluster.

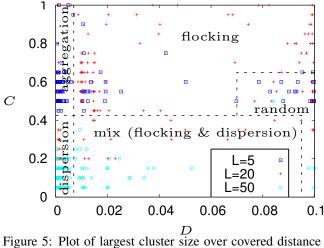

Figure 5: Plot of largest cluster size over covered distance for $L \in \{5, 20, 50\}$.

This measure is more meaningful than just calculating the sum over all agent-agent distances because it allows, for example, to distinguish situations when the swarm is separated in two flocks from situations with uniform distributions. The results averaged over the population of the last generation of the 200 independent evolutionary runs are given in Fig. 4d. For L=5 the median of the largest cluster size is C=0.55(11 agents) and hence relatively big as expected because an agent covers $2s_1$ with its sensors which is 40% of the ring for L=5. With increasing ring length the median of the largest cluster size increases (L < 20) and starts to decrease again for L > 15 until it reaches the low value of C = 0.15(3 agents) for L = 50. Hence, it is very likely to see an aggregated swarm, for example, for ring length L=15 and rather unlikely for L=50. To make a statement concerning the expected frequency of basic collective behaviors, both indicators (covered distance and largest cluster size) have to be considered in combination. For example, flocking is likely to occur for L=15 because fast and well aggregated swarms are frequent for that setting. However, from these results one cannot tell whether both features coexist. In Fig. 5 the largest cluster size is plotted over covered distance for $L \in \{5, 20, 50\}$ and hence allowing to classify the behaviors at least roughly. Aggregation and random behavior is mostly observed for L=5. Dispersion is mostly observed for L=50. Flocking is mostly observed for L=20, whereas it is possible to distinguish between slow moving flocks and fast moving flocks (cf. Fig. 2, flocks can move with different velocities). The behaviors seen in the region 0.07 < D < 0.095, C < 0.42 are inconclusive as they are mixes between flocking and dispersion (i.e., a fraction of the swarm moves as flock and another fraction is dispersed).

Entropy of sensor input

The difficulty of predicting future sensor inputs and minimizing surprise is conceptually connected to information theory by the concept of Shannon entropy. We are interested in the Shannon entropy of the sensor inputs. The entropy is measured for each agent over the whole period of the simulation. For each sensor $X \in \{L1, L0, R0, R1\}$ we measure the probability p_X that the sensor gives a 1 as output and calculate the entropy

$$H_X = -p_X \log_2(p_X) - (1 - p_X) \log_2(1 - p_X). \tag{3}$$

The overall entropy for the considered agent is the average over all sensors $H=\frac{1}{4}(H_{\rm L1}+H_{\rm L0}+H_{\rm R0}+H_{\rm R1}).$ Finally, we average over all individual entropies H of the swarm. The results averaged over the population of the last generation of the 200 independent evolutionary runs are given in Fig. 4e. Note that high entropy is measured for $L\in\{10,15,20,25,30\}$ which corresponds to relatively low fitness for the same ring lengths as seen in Fig. 4b. The inverse accordance of entropy and fitness indicates that diverse sensor input is inherent for intermediate swarm densities.

Control experiments - random genomes

A series of control experiments was done to test whether the results reported above are different from randomly generated behaviors and whether especially the random changes to the action networks by mutations are effective and relevant. A set of 200 random genomes was generated for each ring length $L \in \{5, 10, 15, 20, 25, 30, 35, 40, 45, 50\}$ and a swarm controlled by the respective action networks was simulated for each of them. The performance of these random prediction networks is low for all ring lengths. The median fitness is about 2.0, that is, in average the prediction is correct for two out of the four sensors. This would be expected for randomly generated predictions and equally distributed sensor values which is, however, not necessarily the case as it depends on swarm density and the actual agent behaviors. The entropy of the sensor input for these random behaviors is shown in Fig. 4f. For all ring lengths the entropy of random behaviors is significantly higher than for the entropy of evolved behaviors as shown in Fig. 4e. We also note that the difference between Figs. 4e and f is mostly a mere displacement by $\Delta H \approx 0.4$, that is, the overall shape of the curve is preserved. Hence, the entropy also depends inherently on the swarm density. Given that a randomly generated population is also the starting point of the evolutionary approach, it is justified to say that the evolution of prediction machines minimizes the entropy of the sensor input, too.

The covered distance D is shown in Fig. 4g. It is also invariant to the ring length (no significant differences) and it is in average shorter compared to the evolved behaviors. This is expected because by random control the swarm is unlikely to align and form a flock.

The size of the largest clusters C is shown in Fig. 4h. Large clusters are observed for L=5 as expected because an agent covers already 40% of the ring with its sensors. Still, the system cannot be understood as a mere point process because

the agents might react to each other based on their random controllers. For an assumed uniform distribution of agents we would expect largest clusters of size C=0.4 (8 agents), however, the median is 0.55 (11 agents). With increasing ring length L the size of the largest clusters decreases fast as expected. For ring lengths $L \in \{10, 15, 20, 25\}$ the largest clusters are significantly different and the evolved behaviors discussed above achieve bigger clusters, that is, better organized swarm behaviors. Interestingly, in the case of random behaviors there are a few extreme outliers even for large ring lengths up to L=50 reaching up to C=1 while the evolved behaviors achieve only $C\leq 0.5$ for L>40.

Control experiments - inhomogeneous swarm

Another series of experiments was done to test whether collective behaviors can also be evolved in an inhomogeneous swarm. Before all agents of a particular simulation run (simulated agents on ring) were clones because they shared the same genetic material. Now each agent of a simulation run has its own genome which most likely differs from all other genomes in the swarm. Hence, we merge the two populations that we had before, that is, the population of the evolutionary algorithm is identical to the population in the simulation runs. An advantage of this approach is that the need for computational resources is decreased significantly. Before we were doing 10 repetitions of simulation runs for each genome which sums to 500 simulation runs per generation. Now we do only 10 repetitions of simulation runs per generation because we evaluate all genomes within the same simulation run. However, this approach is ineffective as seen in Fig. 4i. While for ring length L=5 the approach is competitive to the homogeneous approach (cf. Fig. 4b, note different scales), it obtains poor fitness for bigger ring lengths. Also the results for covered distance (Fig. 4j) and size of the largest cluster (Fig. 4k) indicate the poor performance as they are similar to the results of the random genomes (Figs. 4g and h). The evolved inhomogeneous swarms always show random behavior (data not shown).

Discussion and Conclusion

Following the idea of the free-energy principle (Friston, 2010; Friston et al., 2006), that is, minimizing surprise (prediction errors), we have shown that a variety of basic collective behaviors can be evolved by selecting for the ability of making good predictions only. Without generating any direct selective pressure on the actual evolved behavior these typical swarm behaviors emerge depending on the swarm density. Our findings are supported by control experiments. The comparison to random behaviors as generated by random genomes are significantly different. The comparison to evolving behaviors in an inhomogeneous swarm shows that homogeneity in the genomes and hence in the behaviors of a swarm is crucial. However, we do not rule out the possibility to evolve interesting collective behaviors in an inhomo-

geneous swarm if the inhomogeneity is limited (e.g., initializing to a homogeneous population, minimizing the effect of mutations, greedy selection).

The comparison of this approach to the concept of novelty search (Lehman and Stanley, 2008; Mouret and Doncieux, 2009) is interesting. Novelty search generates selective pressure towards unpopulated regions of behavior space, that is, it tries to trigger the evolution of novel behaviors that were not observed before. Our approach of minimizing prediction error seems to implement the opposite, that is, it seems to reward repetitive and hence easy to predict behaviors (on the time scale of a genome's evaluation while novelty search operates on the time scale of generations). Still, the approach is effective and generates a variety of different behaviors. In contrast to novelty search no measure of behavioral distance needs to be defined. The application of this approach to goal-oriented evolution of collective behaviors requires additional research to determine how to guide the evolution. The similarity between the trajectory plots of the evolved behaviors especially for swarms showing flocking (see Fig. 2d) and space-time diagrams of cellular automata (e.g., see Crutchfield and Mitchell (1995, Fig. 2)) is probably more than mere coincidence. Also the concept of particles in cellular automata seems comparable to the concept of flocks here (see Crutchfield and Mitchell (1995, Table 2)). The reported swarm model is spatially 'almost discrete' (agents are displaced by a constant distance) and the agents move in continuous space only due to the continuous initialization of positions and the additive noise. Furthermore, the sensors also discretize an agent's neighborhood spatially (see Fig. 1a), hence the action network might implement simple update rules as seen in cellular automata.

There is also a low similarity to cellular automata in the context of computation 'at the edge of chaos' as discussed in (Langton, 1990; Crutchfield and Young, 1990). The results concerning the best fitness, the covered distance, and the size of the largest cluster (see Fig. 4b-d) indicate that for ring lengths of $L \in [10, 25]$ the evolutionary optimization problem is possibly more difficult and the required behaviors are possibly more complex. For high (L < 10) and for low swarm densities (L > 30) the sensory input is rather monotonous (see results of entropy measurements, Fig. 4e, a majority of sensors give frequently a '1' for high densities or a majority of sensors give frequently a '0' for low densities). For medium densities the sensory input is more likely to change over time and consequently more complex behaviors seem to emerge (e.g., flocking with flocks having different velocities depending on the flock size).

From the perspective of defining optimal conditions for collective behavior, the existence of an optimal density for good swarm performance is known (Hamann, 2013, 2012). The universality of these findings seems to be confirmed by the results concerning the best fitness, the covered distance, and the size of the largest cluster (see Fig. 4b-d).

Future work includes the investigation of how this approach can be utilized also as an approach to open-ended evolution to evolve desired behaviors similar to the concept of novelty search. Another subject will be to investigate whether minimizing prediction error triggers the evolution of positive and negative feedback loops within swarms.

An informational study of the evolution of codes in different population structures

Andrés C. Burgos¹ and Daniel Polani²

^{1,2}Adaptive Systems Research Group, University of Hertfordshire, Hatfield, UK ¹a.c.burgos@herts.ac.uk

Abstract

We consider the problem of the evolution of a code within a structured population of agents. The agents try to maximise their information about their environment by acquiring information from the outputs of other agents in the population. A naive use of information-theoretic methods would assume that every agent knows how to "interpret" the information offered by other agents. However, this assumes that one "knows" which other agents one observes, and thus which code they use. In our model, however, we wish to preclude that: it is not clear which other agents an agent is observing, and the resulting usable information is therefore influenced by the universality of the code used and by which agents an agent is "listening" to.

Introduction

If we consider organisms capable of processing information, then we can argue that they must be able to internally assign meaning to the symbols they perceive in a code-based manner (Görlich et al., 2011). For instance, bacteria perceives chemical molecules in their environment and interprets them in order to better estimate environmental conditions and (stochastically) decide their phenotype (Platt and Fuqua, 2010). Plants detect airborne signals released by other plants, being able to interpret them as attacks of pathogens or herbivores (Heil and Karban, 2010). Therefore, a correspondence between environmental conditions and chemical molecules must be established. It is in this way that Barbieri characterises codes, and he proposes three fundamental characteristics for them: they connect two independent worlds; they add meaning to information; and they are community rules (Barbieri, 2003).

Codes connect two independent worlds by establishing a correspondence or mapping between them. These worlds are independent and thus there are no material constraints for establishing arbitrary mappings. The meaning of information comes exclusively from the mapping: symbols by themselves are meaningless. Finally, the third property requires that the correspondence between the two worlds constitutes an integrated system.

For instance, human languages establishes a correspondence between words and objects (Barbieri, 2003); in bacteria it is between chemical molecules and environmental conditions (Waters and Bassler, 2005). Words (or chemical molecules) by themselves do not have any meaning, they are chosen arbitrarily and any individual of a population can define its own set together with its mapping. However, populations of individuals sharing the same code are ubiquitous in nature. How is it that codes come to be shared by many individuals when, as stated, they are completely arbitrary? This question is what we are investigating in the present paper.

For this work, we assume a simple scenario where organisms seek to maximise their long-term growth rate by following a bet-hedging strategy (Seger and Brockmann, 1987). We know that maximising their information about the environment achieves this (Shannon, 1948; Kelly, 1956; Donaldson-Matasci et al., 2010). Then, individuals obtaining side environmental information from other individuals will have an advantage over those that do not, since they would be able to better predict the future environmental conditions. However, for individuals to be able to communicate with each other, they must be able to translate symbols into environmental conditions, where the

output of these symbols results from an individual's code. The code of an individual is a stochastic mapping from its sensors states to a set of outputs.

For this study, we consider outputs of individuals (or agents) as conventional signs. In semiotics, the science of all processes in which signs are originated, stored, communicated, and being effective (Görlich et al., 2011), two types of signs are traditionally recognised: *conventional signs* and *natural signs* (Deely, 2006). In conventional signs there is no physical constraint on the possible mappings, they are established by conventions. On the other hand, in natural signs, there is always a physical link between the signifier and signified, such as smoke as a sign of fire, odours as signs of food, etc. (Barbieri, 2008).

We are not interested in the particular detailed mechanisms by which an agent implements its code, nor how the agent decodes the outputs of other agents. Instead, we focus on the theoretical limits on the amount of environmental information an agent can possibly acquire resulting from different scenarios of population structure and codes distribution.

The natural framework to analyse such quantities is information theory (Shannon, 1948). However, it does not take semantic aspects into account, it only deals with frequencies of symbols instead of what they symbolise. Codes, on the other hand, add meaning to information, which makes the integration of sciences such as semiotics with information theory non-trivial (Favareau, 2007; Battail, 2009). In the following section, we present an information-theoretic model which incorporates the necessity of conventions by dropping from the model the usual implicit assumption of knowing the identity of the communicating units.

Model

To introduce the model in a progressive manner, let us first consider three agents, θ_1 , θ_2 and θ_3 . Each of these agents depend on the same environmental conditions for survival, which are modelled by a random variable μ . Agents acquire information about the environment through their sensors, which are modelled by random variables Y_{θ_1} , Y_{θ_2} and Y_{θ_3} , all three conditioned on

 μ , for agents θ_1 , θ_2 and θ_3 , respectively. We assume each agent acquires the same amount and aspects of environmental information from μ , *i.e.* $p(Y_{\theta_1}|\mu) = p(Y_{\theta_2}|\mu) = p(Y_{\theta_3}|\mu)$. Let us further assume that the information each agent acquires about the environment does not eliminate its uncertainty, *i.e.* $H(\mu|Y_{\theta_i}) > 0$ for $1 \le i \le 3$. The code of an agent is a stochastic mapping from its sensor states into a set of outputs, and is represented by the conditional probabilities $p(X_{\theta_1}|Y_{\theta_1})$, $p(X_{\theta_2}|Y_{\theta_2})$ and $p(X_{\theta_3}|Y_{\theta_3})$ for agents θ_1 , θ_2 and θ_3 , respectively (see Fig. 1).

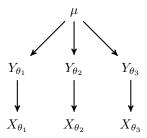

Figure 1: Bayesian network representing the relantionship between the sensor and output variables of three agents.

Let us assume that agent θ_1 perceives only the outputs of agents θ_2 and θ_3 . One possible way of computing the information about the environment agent θ_1 has is to consider the mutual information between μ and the joint distribution of the sensor of θ_1 and the outputs of θ_2 and θ_3 : $I(\mu; Y_{\theta_1}, X_{\theta_2}, X_{\theta_3})$. However, by writing down this quantity, we are implicitly assuming that agent θ_1 "knows" which output corresponds to θ_2 and which output corresponds to θ_3 . Therefore, in this consideration, an agent can theoretically do the translations of the outputs according to some internal model of other agents and infer the mentioned amount of information about its environment.

Indistinguishable sources

For this study, on the contrary, we consider an agent observing other agents' messages, but under the assumption that the originator of a message cannot be identified. In this way, the total amount of information an agent can infer from the outputs of other agents will depend on to which extent it either can identify who the other agents are or can rely on them using a coding scheme that does not depend too much on their particular identity. For instance, if agents θ_2 and θ_3 both

agree on the output for each of the environmental conditions, then agent θ_1 should be able to infer more environmental information than if they disagree on the output for each of the environmental conditions, given that agent θ_1 does not know which of the agents it is observing.

To model this idea, let us assume a random variable Θ' denoting the selected agent, which depends on the same environmental conditions for survival, which are modelled, as above, by a random variable μ . Agents acquire information about the environment through their sensors, which are modelled by a random variable $Y_{\Theta'}$ conditioned on the index variable denoting the agent under consideration, Θ' , and μ . The amount of acquired sensory information of a specific agent θ' about μ is given by $I(\mu;Y_{\theta'})$. As above, the code of an agent is a stochastic mapping from its sensor states into a set of outputs, and is represented by the conditional probability $p(X_{\theta'}|Y_{\theta'})$ for an agent θ' (see Fig. 2).

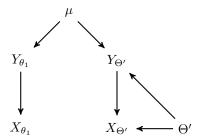

Figure 2: Bayesian network representing the relationships as described above (see text).

However, now we want to model the fact that we do not know which agent is observed. In the case with maximum uncertainty, Θ is uniformly distributed, and then this parametrisation of the codes considers the outputs of all agents in Θ' altogether, such that if we are not observing Θ' , we cannot identify whose agent's output we are observing. In Eq. 3 and Eq. 4 we show two examples of codes for agents θ_2 and θ_3 , while their sensor states are define by the Eq. 2 (Eq. 1 defines the sensors states of agent θ_1). We compute how much information about the environment there is when the outputs of both agents (θ_2 and θ_3) are considered together by agent θ_1 .

$$Pr(Y_{\theta_1}|\mu) := \frac{\mu_1}{\mu_2} \begin{pmatrix} y_1 & y_2 \\ 0.99 & 0.01 \\ 0.01 & 0.99 \end{pmatrix} \tag{1}$$

$$Pr(Y_{\Theta'}|\mu,\Theta') := \begin{cases} \theta_2, & \mu_1 \\ \theta_2, & \mu_2 \\ \theta_3, & \mu_1 \\ \theta_3, & \mu_2 \end{cases} \begin{pmatrix} y_1 & y_2 \\ 0.99 & 0.01 \\ 0.99 & 0.01 \\ 0.01 & 0.99 \end{pmatrix}$$
(2)

$$Pr(X_{\Theta'}|Y_{\Theta'},\Theta') := \begin{array}{c} \theta_2, \ y_1 & 1 & 0\\ \theta_2, \ y_2 & 0 & 1\\ \theta_3, \ y_1 & 1 & 0\\ \theta_3, \ y_2 & 0 & 1 \end{array}$$
(3)

$$Pr(X_{\Theta'}|Y_{\Theta'},\Theta') := \begin{cases} \theta_2, \ y_1 & 1 & 0\\ \theta_2, \ y_2 & 0 & 1\\ \theta_3, \ y_1 & 0 & 1\\ \theta_3, \ y_2 & 1 & 0 \end{cases}$$
(4)

If we assume $p(\theta_2) = p(\theta_3) = 1/2$, and $p(\mu_1) =$ $p(\mu_2) = 1/2$, then if we consider the codes shown in Eq. 3, we have that $I(\mu; Y_{\theta_1}, X_{\Theta'}) = 0.97872$ bits, where Θ' consists of agents θ_2 and θ_3 . However, had θ_2 and θ_3 "opposite" codes as shown in Eq. 4, then $I(\mu; Y_{\theta_1}, X_{\Theta'}) = 0.9192$ bits, which is exactly $I(\mu; Y_{\theta_1})$, that is, $I(\mu; X_{\Theta'}|Y_{\theta_1}) = 0$ bits (agent θ_1 cannot acquire any side information from the outputs of agents θ_2 and θ_3). We should note here that the sensor states y_1 and y_2 of agents θ_2 and θ_3 in the conditional probability shown in Eq. 3 and 4 refer almost deterministically to the same environmental condition, and therefore the loss of side information is thus entirely due to the incompatible codes. The conditional probabilities of sensor states given the environmental conditions further defined throughout the paper are also assumed to be almost deterministically.

Population information

The model shown in Fig. 2 considers the environmental information of agent θ_1 , ignoring its own output X_{θ_1} . Nevertheless, agents ignoring their outputs is contrary to our assumption over the sources of the outputs. To incorporate this option in the model shown in Fig. 2, we could consider the state space of Θ' as the set $\{\theta_1, \theta_2, \theta_3\}$. Then, to express not only the environmental information of agent θ_1 , but the average environmental information of the whole population, we can parametrise the sensors of the agents by a random variable Θ (defined over the same state space, representing the same set of agents as Θ'), such that

 $p(Y_{\Theta}|\mu,\Theta) = p(Y_{\Theta'}|\mu,\Theta')$ (i.e., $Y_{\Theta'}$ is i.i.d. to Y_{Θ} , and vice versa).

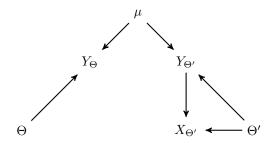

Figure 3: Bayesian network representing the sensor variables of a set of agents indexed by the random variable Θ , and the sensor and output variables of a copy of the set of agents indexed by Θ named Θ' .

In this way, the average environmental information of a population of the agents selected by Θ is given by $I(\mu; Y_{\Theta}, X_{\Theta'})$ (see Fig. 3). This measure can be consider as the objective function to maximise in our model. However, we would be making two important assumptions: first, this objective function assumes agents have access to the environmental conditions μ , which they indirectly do but only through their sensors; and second, every agent would perceive the output of every other agent, including itself. In this work, we instead simplify the model in that we propose agents following a behaviour such that it maximises the similarity of their outputs (via their codes) with those of which the agent perceives. A consequence of this behaviour is that the average information about μ is also maximised. In addition, we will introduce a potentially flexible "population structure", so that we can specify which agents interact with which.

Code similarity

First, we introduce a copy of the codes of the agents, such that when we instantiate the variables X_{Θ} and $X_{\Theta'}$, the probabilities are the same. The structure of the population is then given by $p(\Theta, \Theta') = p(\Theta)p(\Theta')$. However, the conditional independence of Θ and Θ' restricts significantly the diversity of the structures that can be represented. In order to model a general interaction structure between agents, we consider $p(\Theta, \Theta')$ not independent, as shown in the Bayesian network in Fig. 4, where we introduce a helper variable Ξ .

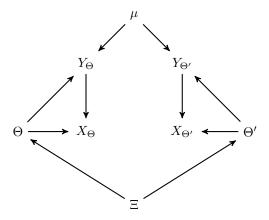

Figure 4: Bayesian network representing the relantionship of the variables in the model of code evolution. $Y_{\Theta'}$ is an *i.i.d.* copy of Y_{Θ} and $X_{\Theta'}$ is an *i.i.d.* copy of X_{Θ} . Θ' covers the same set of agents as Θ , but its probability distribution is not necessary the same.

We can interpret our objective function $I(X_\Theta; X_{\Theta'})$ as the average code similarity of a population of agents according to the population structure $p(\Theta, \Theta')$. For instance, if two agents cannot exchange outputs in a given structure, then there is no gain (in the value of the objective function) in adopting similar codes for these two agents.

If we consider our system as a process in time, then at each time-step two agents are chosen according to $p(\Theta, \Theta')$. Agent Θ reads the output of agent Θ' (generated via its code, which is *i.i.d* over time), and let us assume that it stores the pair $(Y_{\Theta}, X_{\Theta'})$, i.e. its current sensor state together with the perceived output. If this is repeated a large number of times, then the total amount of environmental information that can be inferred from the collected statistics by the population is bounded by $I(\mu; Y_{\Theta}, X_{\Theta'})$. This is the theoretical limit to which we refer in the introduction, and for this study we are not interested in how the inference is computed. However, we implicitly assume that agents decode the perceived outputs according to their codes.

Distance between two codes

In order to visualise the evolution of codes, we define the distance between the codes of two agents θ_i and θ_j as the square root of the *Jensen-Shannon divergence* (Wong and You, 1985; Lin, 1991) be-

tween them. This measure has the property that $0 \leq JSD(\theta_i,\theta_j) \leq 1$ when \log_2 is used, and the square root yields a metric. Let us note that this distance requires the sensor states Y to be named identically (for the corresponding states of μ) among agents in order to be meaningful. As we stated above, this is (closely) the case in all our experiments. This requirement over the sensor states discards the possibility of using other measures such as mutual information.

Methods

To illustrate the behaviour of our model, we consider three different scenarios, which are described in the Results section. The common parameters for the first two experiments are the following: the population consists of 25 agents (the small number was chosen to avoid high computational costs); the amount and quality of the acquired sensory information is the same for every agent, that is $p(Y_{\theta_i}|\mu) = p(Y_{\theta_j}|\mu)$ for every $i,j \in [1,25]$. For the last scenario, the only difference is that we consider only 15 agents.

The optimisation algorithm used in the following experiments is CMA-ES (Covariance Matrix Adaptation Evolution Strategy), which is a stochastic derivative-free method for non-linear optimisation problems (Hansen and Ostermeier, 2001). We utilised the implementation provided by the Shark library v3.0.0 (Igel et al., 2008) with its default parameters, which implements the CMA-ES algorithm described in (Hansen and Kern, 2004). The evolutionary algorithm used for optimisation does not intend to represent the actual evolution of the codes. Instead, we are interested in the solutions of this optimisation process, which are representative of the possible outcomes of evolution.

To visualise the evolution of the codes of the agents, we use the method of multidimensional scaling provided by R version 2.14.1 (2011-12-22).

Results

In this section, we analyse the outcome of three different scenarios where code similarity is maximised. While the outcomes are particular for one

simulation, they are illustrative of the richness that the model is able to capture, which is described for each scenario. The outcomes are typical solutions, and we cannot perform statistics over simulations since the many solutions are qualitatively different.

Well-mixed population

In the first scenario, each agent θ_i perceives the output of every other possible agent θ_j with the same probability, that is $p(\theta_i,\theta_j)=1/25^2$ for every $i,j\in[1,25]$. The maximum average code similarity is bounded by $I(Y_\Theta;Y_{\Theta'})=1.71908$ bits, which is achieved under two conditions: first, every code must be a one-to-one mapping; second, the code must be universal. This is indeed the outcome of the performed optimisation, as we show in Fig. 5: the optimised codes (blue points) converged into a universal code (the distance between any of them is zero). Each red point correspond to an initial code.

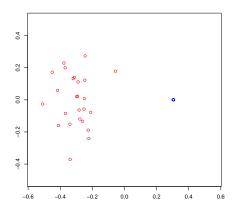

Figure 5: 2-dimensional plot of code distance: red points are codes at the beginning of the optimisation process; blue points are codes at the end of the optimisation process (where the distance between every pair of codes is zero).

The resulting code adopted by the population is a one-to-one mapping between sensor states and outputs, and any of the 24 possible one-to-one mappings is a global maximum (there are 4 sensor states and 4 possible outputs). However, it is still interesting to briefly analyse the possible paths towards a universal and optimal code. In Fig. 6, we show the distribution of the adopted codes by the agents of the population in a moment of the optimisation process where the average code similarity is $I(X_{\Theta}; X_{\Theta'}) = 1.18276$ bits. Here, the most popular code is the suboptimal code shown

in Fig. 6 (a). This results from the particular initialised codes, driving the agents temporarily towards a suboptimal code. However, once any of the many-to-one codes becomes (nearly) universally adopted, then any code's deviation improving code similarity will eventually drive the convention towards optimality. The fact that it does not need simultaneous changes in the code increases the likeliness of improving the code similarity.

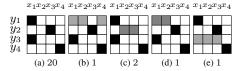

Figure 6: Representation of the codes p(x|y) by a heat-map using inverse grayscale. For each evolved code, we output the number of agents adopting it. This code distribution was achieved with 25 agents in a well-mixed population.

Spatially-structured population

In another set-up, we assume the agents are structured in a 5×5 grid, where $p(\theta,\theta')=1/105$ if θ and θ' are neighbours or when $\theta=\theta'$. After randomly initialising the codes, the performed optimisation plateaued on an average code similarity of $I(X_\Theta;X_{\Theta'})=1.13536$ bits. As in the former scenario, here the optimal solution is also a universal code with a one-to-one mapping. However, in this case, the result is not a universal code, as can be appreciated in Fig. 7. Spatially structure populations are sensitive to the initial codes and how codes are updated.

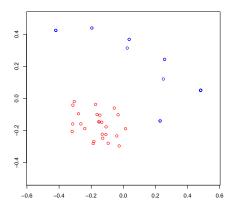

Figure 7: 2-dimensional plot of code distance: red points are codes at the beginning of the optimisation process; blue points are codes at the end of the optimisation process.

The resulting code distribution among the population is shown in Fig. 8, with 8 different codes in the population. Different from the well-mixed population structure, in a spatially structured population the pressure to agree on a code occurs only between neighbours. A consequence of this is that many local conventions are established within neighbourhoods, and once this situation is reached, to improve the total code similarity, some simultaneous changes to the agent's codes would be needed. For instance, the code shown in Fig. 8 (e) could increase the average similarity of the population if $p(x_2|y_1) = 1$, as it is in the rest of the codes. However, for this to happen (in this particular case), at least two agents need to change their code simultaneously (otherwise the average similarity decreases), which makes the deviation from the resulting code distribution unlikely.

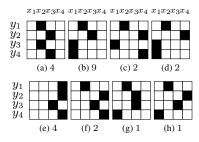

Figure 8: Representation of the codes p(x|y) by a heat-map using inverse grayscale. For each evolved code, we output the number of agents adopting it. This code distribution was achieved with 25 agents in a grid structure.

Free structure

For our last scenario, we let the structure evolve with the codes without any constraint. In this case, the resulting average code similarity is nearly optimal, but the code is not necessarily universal. This is because, when the structure is not fixed, agents form roughly disconnected clusters of related codes. In this process, the interaction probability of agents with unrelated codes will vanish, decreasing the entropy of the population structure $H(\Xi)$ (see Fig. 9). However, once the clusters are formed, if it is not a single isolated agent (such that nobody perceives its output), then each cluster conform a universal code within itself. In the latter case, the entropy of the structure can increase if the agents within a cluster perceive the outputs of all other agents also within their clusters (periods where $H(\Xi)$ increases on in Fig. 9).

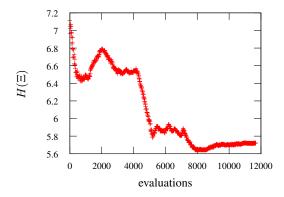

Figure 9: Evolution of the entropy of the population structure.

This is exemplified by the code distribution and population structure we obtained (see Fig. 10).

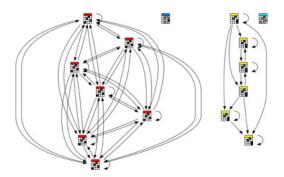

Figure 10: Each node in the graph corresponds to the code of an agent. There is a weighted edge between agent θ_i and θ_j if $p(\theta_i,\theta_j)>0$ (which is the weight). The temperature colours on top of the nodes indicate the amount of environmental information they would contribute to any agent perceiving only that agents output.

Discussion

We considered three different scenarios of code evolution: in the first one, all agents perceived the outputs of all other agents, including itself. We argued that two main stages of evolution can be recognised: in the first stage, a universal code is established, which can be optimal or not. If it is not optimal, then a second stage will achieve optimality. The same result was obtained in (Vetsigian et al., 2006), in a model of the evolution of the genetic code (represented as a probabilistic mapping between codons and amino acids), although universality and optimality were simultaneously achieved.

In the mentioned work, which developed further the ideas of (Woese, 2002, 2004), the authors argue that the universality of the genetic code is a consequence of early communal evolution, mediated by horizontal gene transfer (HGT) between primitive cells. In this evolutionary process, they argue, larger communities will have access (through the exchange of genetic material) to more innovations, leading to faster evolution than smaller ones. Then, "it is not better genetic codes that give an advantage but more common ones" (Vetsigian et al., 2006). Although their model does not explicitly show this property, it is captured in our model. We show that a more common, but not optimal code is widely adopted within a population (see Fig. 6). However, in our model, a code imposes itself as universal not because it provides access to more innovations (in our model there is no "code exchange", only the outputs are shared), but because the population structure forces the adoption of the most popular code. After this stage, further changes in the code of the agents eventually lead to optimality.

In another related work, (Oudeyer, 2005) explored the origins of language in a scenario consisting of artificial agents with a coupled perception and production of speech sounds. Although this work is focused on plausible mechanisms for the origin of language, it assumes the same similarity principle as we do (hearing a vocalisation increases the probability of producing similar vocalisations), arriving to the same outcome (a universal language, or code).

Our second scenario, where the structure of the population is a grid, showed how establishing local conventions in early stages of evolution constrains the outcome of the code distribution, since to reconcile different conventions, several simultaneous changes are needed. On the other hand, in our third scenario, where we let the structure of the population change simultaneously with the codes themselves, such situations are avoided by "disconnecting" clusters with dissimilar conventions. This property enhances evolution, and can potentially lead to the adoption of several different conventions within an (increasingly fragmenting, or "speciating") population.

The evolution and establishment of conventional codes as defined by Barbieri could be interpreted, in the widest sense, as a form of cultural evolution. While communication between individuals of a population opens up the possibility of "signal cheaters", our model does not allow such behaviour, since the code producing the outputs functions, implicitly, as the interpreter of the perceived signals.

Conclusion

In the proposed model, we introduced a key assumption which allowed us to evolve, for some structures, universal and optimal codes. This assumption states that an agent cannot distinguish the sources of the outputs it perceives from other agents. Following from this, a universal code will necessary introduce semantics by relating symbols to environmental conditions (via the internal states of the agent). Our model proposes an information-theoretic way of measuring the similarity within a population of codes.

In this work, we proposed, as an evolutionary principle, that agents try to maximise their side information about the environment indirectly by maximising their mutual code similarity. This behaviour produces several interesting outcomes in the code distribution of a structured population. Depending on the population structure, it captures the evolution of a universal and optimal code (well-mixed population structure), while also the evolution of different codes organised in clusters (in a freely evolving structure), which allows the establishment of optimal as well as suboptimal conventions.

In between Schelling and Maynard-Smith

Hugues Bersini

Abstract

In the history of agent-based/Alife simulations helping to better understand some unexpected social consequences emerging out of interactive individual behaviors, two models have become quite celebrated: the Schelling's segregation model and the Maynard-Smith's emergence of cooperation in an albeit very defective world. In this paper, we explore a simulation at the crossroad of these two models. We show how in a bi-color society in which individual can move according to their neighborhood "colored" composition (reminiscent of the original Schelling's model), one further way to favor cooperation is to encourage "communitarian" behavior i.e. allowing individual to move, compose clusters of similar color and evolve a cooperative behavior restricted to partners of the same color. In brief, our results not so surprisingly tend to show that communitarian cooperation and segregation evolve hand in hand.

Introduction

Despite or on account of its simplicity, the Schelling's segregation model (Schelling, 1978) has become quite a classic of the sociological literature. It surprisingly shows how even a weakly communitarian attitude can drive to a very segregated society. The simulation on a 2-D board goes as follows. Each agent has one out of two colors. It is located on one site and the board contains a small fraction of empty sites. The neighborhood is a Moore's one. At each time step, an agent moves (and occupies a free location picked randomly) if more than two of its neighbors are of different color. The simulation shows (like in figure 1) how clusters of agents with same color rapidly percolate through the board despite a somewhat "tolerant" moving condition.

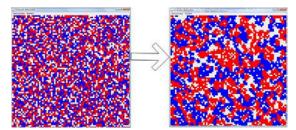

Figure 1: Schelling's segregation simulation: the starting and the final boards. Clusters of same color agents emerge despite weak communitarian rules of movement.

In another quite famous simulation (initially due to Maynard-Smith then further elaborated by Novak and many others – (Maynard-Smith, 1982; Novak, 2006; Novak et al., 1994)) based on the prisoner dilemma game, two types of interacting agents compete for occupying the full board: cooperators and defectors. The agents don't move but switch their type in time in order to imitate their most successful neighbors. At each time step, first all agents play a prisoner dilemma game with all their neighbors and cumulate their fitness according to the rule of the game indicated below.

Agent1/Agent2	Cooperator	Defector
Cooperator	1,1	0,1+x
Defector	1+x,0	0,0

As indicated in this gain matrix (and similar to the values tested by (Novak, 1994; 2006)), the pressure of "defection" as compared to the cooperative attitude depends on the value of "x". Then, at each time step also, an agent i selected randomly changes its "type" and imitates its neighbor j according to the following probability:

$$P_{i->j} = (f_i - f_i)/(F_{max} - F_{min})$$
 $if f_i > f_i$

Where f_j is the cumulated fitness of neighbor j, f_i the cumulated fitness of the agent to update and the denominator is based on the greatest and the lowest cumulated fitness of all agents. In agreement with results widely discussed in (Novak, 2006), whereas not so surprisingly defection invades the world for x > 0.25 and cooperation for x < 0.05, a much more interesting phenomenon (like shown in figure 2) unfolds for intermediary defection such as for x=0.15.

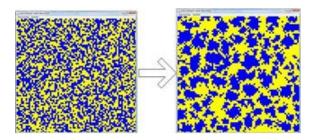

Figure 2: Maynard-Smith and Novak's evolutionary game simulation: cluster of cooperators can survive while surrounded by defecting agents.

In this simulation, clusters of cooperators can still prevail while being besieged by defectors. The way cooperation can emerge in a world subject to a very defective pressure has attracted a huge attention these last years. As Novak synthetizes in (Novak, 2006), common to the many possible alternatives such as "spatial clustering" (the one studied in this paper), "tit-for-tat", "social scale-free network", "group selection", always underlie the very intuitive idea that any possibility to make cooperators restrict their interaction with other similar cooperators favor their resistance to defection. For instance, both "tit-for-tat" and "spatial clustering" condemn defectors to reciprocate, the first in time and the second in space, and suppress them out. Reciprocation instead is much more advantageous for cooperators.

In this paper, we explore a further interesting alternative road, somewhere in between Schelling and Maynard-Smith, in which the simulation allows agent of two colors to successively move and play the interactive game. Our experimental results show how agents, simultaneously "movers" and "cooperators", can drive the world to both "segregate" and privilege a restricted form of "cooperation" with same color agents. The next chapter will describe the simulation in all details and the third one will present the experimental outcomes of this simulation.

The simulation

The following UML class and sequence diagrams are the best way to expose the different parts and the behavior of our simulator. In (Bersini, 2012), the same two UML diagrams (for a first and easy introduction to UML see (Fowler, 2003)) are exploited to respectively explain the Schelling and the Maynard-Smith/Novak simulations. Let's first describe the various classes of the code as presented in the first diagram. The world is a toroidal two dimensional grid composed of sites. The neighborhood is the Moore's one. Each agent is located on one site and some sites are left unoccupied. Each agent has one out of two colors. The agents can behave according to two main behavioral super classes: "Movement" and "Interaction". The "Movement" cares for the Schelling's part of the model while the "Interaction" cares for the Maynard-Smith's part of it. Let's first deal with the easy part: the movement behavior. Three sub-behaviors are possible.

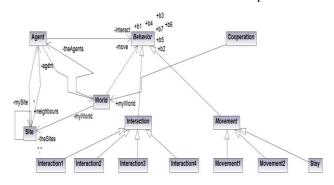

Figure 3.1 Class diagram of the model

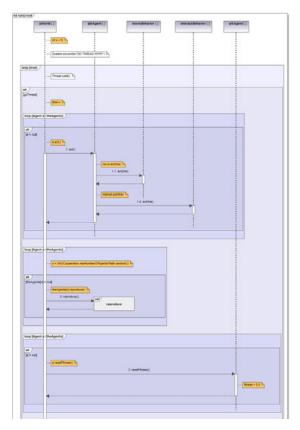

Figure 3.2: Sequence diagram of the simulation

- Movement1(stay): Paradoxically, this is the "immobile" behavior. The agent chooses not to move.
- Movement2: The agent moves to a random free site if its neighborhood is composed of a majority of agents of its color (this is the "anti-communitarian" attitude).
- 3. *Movement3*: The agent moves to a random free site if its neighborhood is composed of a minority of agent of its color (this is the communitarian attitude).

Notice that in the case the neighborhood is composed of an equal mix of colors, the agents can randomly decide to move or not. The two last behaviors (the real movements) receive a fitness penalty so that the "immobile" strategy is selectively always favored.

Now let's deal with the more subtle "interaction" part. Four sub-behaviors turn out to be possible, the most original being the last two.

- 1. Interaction1: Cooperate with all agents.
- 2. Interaction2: Defect with all agents.
- 3. *Interaction3*: Cooperate only with agents of the same color, defect with all others.
- 4. *Interaction4*: Cooperate only with agents of a different color, defect with all others.

Obviously the most innovative part of the simulation with respect to the existing models resides in these last two behaviors, which allow a more restrictive form of interaction: a "communitarian" or an "anti-communitarian" attitude. The fitness values are exactly the same as for the simpler original case: cooperation award = 1, defection award = 1 + x, and a cooperator facing a defector gets 0. Again, the value of "x" will be varied in between 0 and 0.25 (between full defection and full cooperation) and again, as the next section will show, the most intriguing and interesting results are obtained for the intermediary range (for which cooperation hardly begins to emerge despite the strong pressure of defection). Seven subbehaviors turn out to be possible but, at the end, every single agent behavior is composed of a pair of one "movement" and one "interaction" sub-behavior (out of twelve possible pairings). Any agent first moves then interact.

The sequential unfolding of the whole simulation can be easily grasped out of the sequence diagram. First, the "world" class asks all agents to act. Then, each agent's action consists in the succession of the two sub-behaviors: first the movement then the interaction. The true movements slightly negatively impact the fitness but the most important fitness contribution is due to the interaction between the agents, in agreement with the classical prisoner dilemma fitness table.

Finally, the agents (while always keeping their color) adapt their type by imitating their most successful neighbors, following the same probability as explained above. When an agent adopts the behavior of its fittest neighbor, it copies both sub-behaviors: the movement and the interaction ones.

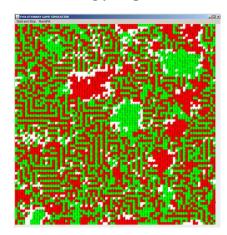

The simulation is run for a given number of time steps, in general until an almost stable configuration (visually assessed) is reached. At the beginning of the simulation, the world is randomly filled with agents of the two colors.

While Novak et al (1994), fascinated by the fractals and kaleidoscopes figures obtained by their simulations, have always tend to favor a deterministic (agents imitate their most successful neighbor) and synchronous form of evolutionary game simulation (all agents play the game then all agents imitate their neighbors), the simulation here adopts instead a stochastic and asynchronous form of updating. In (Bersini and Detours, 1994), it has definitely been advocated why this type of simulation and updating rule should always be preferred over the alternative one. Many irrelevant computational artifact effects are avoided but mainly, it is very hard to conceive natural objects which simultaneously update in time according to a precise central clock.

Experimental results

The experimental results of our simulation will be shown in two forms: first the final board then the evolution in time of the statistical distribution of all seven sub-behaviors among the agents. This second set of dynamical data testifies of the relative evolutionary fitness success of all sub-behaviors and is very reminiscent of the measure of evolutionary activities proposed in (Bedau and Packard, 1992).

1) x = 0 (A strongly cooperative world)

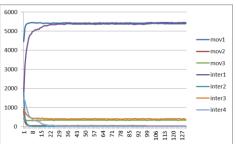

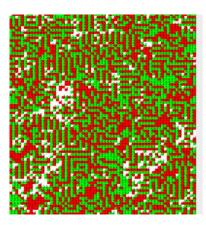

Figure 4: The results in the case of a very cooperative world.

The world remains well mixed and, without surprise, the two winning sub-behaviors are "movement1" (i.e. stay immobile) and "interaction1" (cooperate with all). There is a very timid background activity of the other sub-behaviors that can explain the appearance of tiny local clusters (due to movement3) and "geometrical figures" (due to movement2). While the appearance of clusters is obvious to explain, it is equally easy to understand why the geometrical parallelizing of lines of same color agents is the best way to satisfy the anti-communitarian attitude (maximum of neighbors of different color).

2) x = 0.30 (A strongly defective world)

Again, with no big surprise, the winning sub-behavior is really "inter2" (defect with all). Both "movement1" and a bit of "movement2" (that justifies the appearance of the geometrical configuration) slightly manifest themselves. The reason why the "movement2 (i.e. the "anti-communitarian" displacement) prevails over the opposite one when general defection is the main outcome will be explained in the next paragraph.

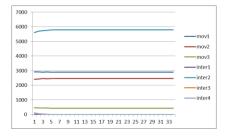

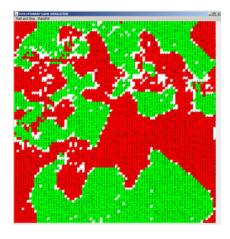

Figure 5: the results in the case of a very defective world.

3) x = 0.10 (An intermediary subtle world)

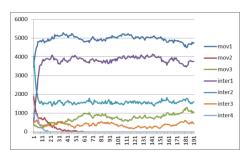

Figure 6: The results in the case of an intermediary world

Such as with the Novak's inspiring original simulation, this intermediary strength of defection leads to the most interesting collective phenomena. Let's discuss the main outcomes. First of all (and this is perhaps the most surprising and interesting effect), a look at the resulting board shows how the world has now become highly segregated. The agents have chosen to cluster according to their color, though no fitness pressure encourages them to behave so (even the contrary). Additionally, the selection of the most adaptive behaviors is much more fluctuating in time than in the previous case due to the continuous competition between defectors and cooperators. The two most successful subbehaviors are "staying immobile" and "cooperate with all", although the third one "defect with all" does not completely vanish. Indeed, such as with the original model (in the absence of any displacement), the intermediary value of the defection pressure leads to a mix of defection and cooperation where for the cooperators to survive they need to self-protect themselves by composing encapsulating clusters.

However, one key difference with the two previous simulations is the presence of two other less successful but nevertheless surviving sub-behaviors: "move3" and "inter3" i.e. change location in the case of a too distinct neighborhood (the communitarian movement) and restrict your cooperative behavior only with agents of the same color (the communitarian cooperation). Moreover, their relative evolutionary importance seems to fluctuate in a very similar way tending to show that they might together characterize the same little ratio of agents. Such as with the Schelling's original model, the fitness success of "move3" is obviously the key reason for the segregation to take place. If new simulations are run, but now in the presence of a fitness penalty for the move much more important, no segregation can take place, while in the case of a less penalized movement this segregation and the success of the "communitarian interaction" are even stronger.

Can we intuitively explain what's going on here and why such segregation occurs although no fitness gain is provided for it (since this movement is penalized).

First, the main result of the Schelling's model is that as a matter of fact only a small ratio of moving agents is enough for the world to become quite segregated. It is clearly the case here since few agents chose to move but with dramatic effects. But, why is it the pair "move3/inter3" that takes the lead and not the alternative pair "move2/inter4" (i.e. the anticommunitarian attitude)? Why the final spatial configuration is filled with clusters and not with geometrical figures? If any agent decides to cooperate only with distinct agents, it is quite simple to understand why its cumulative fitness will be lower than in the communitarian case. Simply, the number of such partners to cooperate with will always be lower in a not segregated world. In other words, a mixed population offers less fitness gain opportunity for "anti-communitarian cooperators" than a very segregated world offers for "communitarian cooperators". When room is left for them to compete, the pairing "move3/inter3" is much more likely to defeat the pairing "move2/inter4".

This same reasoning equally justifies the appearance of the geometrical figures and the relative success of the anticommunitarian attitude in a very defective world (the previous result). This spatial configuration restricts the number of partners each agent can cooperate or defect with in the case of the interaction rules "inter3" and "inter4". For a defector, it is better to defect with less than more (while for a cooperator it is better to cooperate with more than less). Then, one can understand the relative success of the anti-communitarian behavior in a defective world and the relative success of the communitarian attitude as soon as room is left for any form of "reciprocal cooperation".

Figure 7 shows the relative importance of the two movements (communitarian and anti-communitarian) for varying degree of the value 1+x. One can see the initial gradual growing in importance of the communitarian movement as long as cooperation pays and the inversion taking place as soon as the general defective behavior takes the lead (at x = 0.20).

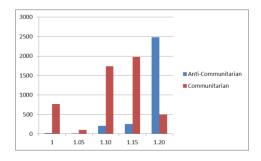

Figure 7: Relative evolutionary success of the anti-communitarian and the communitarian movements ("mov2" and "mov3" above)

The main original result of merging the displacement and grouping strategy of Schelling together with the cooperative/defective evolution of Maynard-Smith/Novak is to facilitate a new route for cooperation favorable to agents which chose to restrict their cooperative attitude to others sharing their same identity.

Conclusions

In a fierce attack against Darwin's natural selection, two philosophers (Fodor and Piattelli-Palmarini, 2006) deny to the classical theory the possibility to distinguish between a trait that has been selectively favored (the heart as a pump) and one that, just by chance, comes together with the previous one. This other trait, although successfully surviving in time, will have never been selected for (e.g. the heart makes noise). Although these attacks have been intensively countered and the book been strongly criticized, it might nonetheless be still valuable to singularize adapted but not per force adaptive traits.

In the model just described, what our simulation results tend to show is that the "segregation behavior" just evolves as a kind of "free-rider" (to re-use the two philosophers terminology) of the "communitarian attitude". This segregating behavior does not appear to be really selected for (since its fitness is even negative) but benefits of the high fitness of the interactive behavior it positively correlates with.

The communitarian attitude is obviously well known to be a definitive very salient trait of human nature. While the Schelling's model never really justified why even this very tolerant regrouping would occur, the simulation discussed in this paper shows that the cooperative gain and the increase in cooperative opportunities (against the prisoner dilemma defective trap) might be the real pressure force that encourage people to assemble according to some distinctive traits (color, religion, social classes, ...).

Extended Abstract

Hierarchy among social animals is ubiquitous, and affects the social structures of gregarious species not only by interaction among species within the population, but also through other social forces such as mating, nesting location, amount and the quality of food they receive, or reproductive success. Since T. Schjelderup-Ebbe developed the structural definition of dominance and hierarchy in 1922 (see, e.g., Drews (1993)), different aspects of this social behavior have been addressed. However, exactly how hierarchies can emerge and be maintained among social species is still a conundrum. To investigate this issue, here we analyze a population of autonomous agents ("animates") through the course of evolution. The results of our experiments demonstrate the importance of memory and brain plasticity for the emergence of hierarchy and dominance behavior.

Living in groups has many advantages over living alone. Strength in numbers (Brown, 1996), division of labor (Goldsby et al., 2010), collective hunting (Alexander, 1974), protection via swarming (Olson et al., 2013) are only some of those advantages justifying the evolutionary advantage groups have over solitary living individuals. It has often been remarked that living in groups requires a higher level of organisation than the solitary mode, and provides the driving force for the evolution of more complex cognitive systems in social animals (Ashforth and Mael, 1989). In many cases, hierarchies are used to organize the group, with dominant animals leading and submissive animals falling in line (for a definition of hierarchy see (Drews, 1993)). While social insects like bees or ants solve this organization problem by literally making different organisms (such as queens) to reproduce and workers to perform the labor (Robinson et al., 2008), mammals usually establish their hierarchy using phenotypic traits like strength, aggression, or age (Alexander, 1974; Gauthreaux Jr, 1978). In addition, such hierarchies are usually robust to noise and damage. For example, in case those traits change (or animals die) the submissive animals can become dominant or else animals can reorganize the hierarchy altogether. The ability to robustly reorganize hierarchies requires animals to potentially take on every rank or role in the hierarchy. Here we evolve the capacity to form hierarchies spontaneously (and to reorganize them on the fly) in groups of animats that can communicate on multiple levels (visually, as well as via signalling) with the goal of creating robust collaborative groups. Our animats are controlled by evolvable Markov Gate networks (MGN) (Edlund et al., 2011). Each gate in an MGN is an arbitrary probabilistic (or sometimes deterministic) logic gate, whose function is determined by a set of evolvable probabilities. Here, we introduce in addition gates that can perform simple stack, threshold, counting, and temporal buffering tasks. These MGNs were embodied in a virtual robot (animat) roaming a 2d plane. Animats can turn 90 degrees left and right, move forward, wait, as well as signal a single bit. Sensors allow them to see objects in front of them, the direction it is facing, and to listen to the signals of other animats in their group. Besides these sensors, each animat can use 32 internal bits for computation. We evolve a population of 100 animats

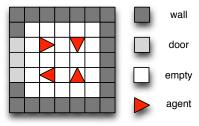

Figure 1: Layout of the test environment (arena). Red triangles: animats. Walls are in dark gray and the door in light gray. The rest of the room is empty (white).

using a classic Genetic Algorithm for 100,000 generations. Animats establish a hierarchy spontaneously by choosing an order they first leave the room. When placed in the same room in subsequent trials, they must leave it in the same exact order. However, these decisions must be made by agents with the same exact brain, that is, the different roles cannot be taken on genetically: they have to be made using information that the agents leave in the arena. The fitness of an animat's genes is determined each by placing four identical copies (clones) of the animat with random orientations in a rectangular room that is enclosed by a wall with a large door on one side of the room (see figure 1). Every time an agent leaves the room by moving through the door, it is removed from the simulation. After the agents have established the hierarchy via the first trial, they are put back randomly to the start locations with random orientations, and accumulate fitness if they leave the room in the same exact order as dictated by the hierarchy in the subsequent 19 trials. Based on the given information, we can write the fitness function as:

$$w = \frac{1}{20 \times 4} \left[\sum_{i=2}^{N} \sum_{j=1}^{4} \delta(v_{ij} - v_{1j}) \right] (1)$$

where $N \leq 20$ is the trail number, v_{ij} is the label of j^{th} robot in the i^{th} round of task, v_{1j} is the label of j^{th} agent the first time agents leave the room, and $\delta(.)$ is Dirac's delta function. Each test is repeated four times for each animat, where the brains are completely reset so that the first order of exits will be random in each test. At the end of each evolutionary experiment, we reconstruct the line of descent (LOD) (Lenski et al., 2003). To test which method of communication was used to establish the order, we re-evaluate the fitness of each agent on the LOD while impeding vision, signalling (or both) by blocking the sensors. The evolutionary experiment was repeated 100 times, and only 11 out of those 100 (from now on called best) evolved a population with a best fitness higher than 0.825 (arbitrary cutoff proportional to getting seven out of eight ranks right), while the average final fitness over all 100 experiments is about 0.625 (Hintze, 2014). This suggests that the task is rather hard to evolve. We find a significant loss in fitness when making

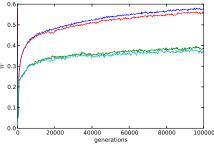

Figure 2: Average fitness (W) on the line of decent over 100.000 generations for all 100 replicates in blue. Fitness for the same bots when they were invisible to each other in green, when they were unable to use their communication channel in red, and when both senses were impaired in least blue.

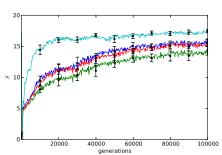

Figure 3: Average success to get individual ranks correct (S) on the line of decent for those eleven best bots. Success that the rank is correct for the first bot in blue, for the second bot in green, for the third bot in red, and for the last bot leaving the room in light blue. In black the standard error.

bots invisible to each other (see figure:2 green), and almost no additional loss in fitness when we block the communication channel (see figure:2 red), indicating that the communication channel is of no important in organizing the hierarchy, and vision alone suffices. It has been argued that the formation of hierarchies requires organisms to evolve submission

first (Alexander (1974)). While in our experiment it is not obvious if bots leaving the room early are dominant over those that leave the room later or the other way around, we find that bots evolve to wait first. When testing the 11 best bots, we find a much better success rate for the last bot leaving the room early on in evolution (see figure:3), than on all other ranks. Only later in evolution the other ranks catch up. We showed that one can evolve virtual clonal bots to form a hierarchy and maintain it over an extensive period. Instead of having distinct properties, these bots were identical and needed to establish an internal representation of a rank through memory and communication. Even though this is a very simplistic environment, we think that this is an important stepping stone towards autonomous self organisation in virtual bots with implications to embedded systems. In the future we plan on studying the robustness of these systems, and how different reward or selection schemes (individual vs. group level selection) effect the formation of hierarchies.

REDS: An Energy-Constrained Spatial Social Network Model

Alberto Antonioni¹, Seth Bullock², Marco Tomassini¹

¹Information Systems Department, Faculty of Business and Economics, University of Lausanne, Switzerland ²Institute for Complex Systems Simulation, University of Southampton, United Kingdom

Abstract

The organisation of living systems is neither random nor regular, but tends to exhibit complex structure in the form of clustering and modularity. Here, we present a very simple model that generates random networks with spontaneous community structure reminiscent of living systems, particularly those involving social interaction. We extend the wellknown random geometric graph model, in which spatially embedded networks are constructed subject to a constraint on edge length, in order to capture two key additional features of organic social networks. First, relationships that span longer distances are more costly to maintain. Conversely, relationships between nodes that share neighbours may be less costly to maintain due to social synergy. The resulting networks have several properties in common with those of organic social networks. We demonstrate that the model generates nontrivial community structure and that, unlike for random geometric graphs, densely connected communities do not simply arise as a consequence of an initial locational advantage.

Introduction

The structure of living systems is neither random (where every system element interacts with a random sub-set of other elements) nor regular (where elements interact with neighbours on a lattice). Instead, such systems tend to exhibit complex structure typically featuring clustering and modularity. No doubt much of the detail of this structure arises for reasons that are specific and idiosyncratic to each case. However, self-organisation in simple systems suggests that some characteristic structure may be relatively generic and may arise as a result of fairly simple factors—indeed this type of self-structuring may serve as an important foundation for subsequent evolution and development (e.g., Boerlijst and Hogeweg, 1991; Di Paolo, 2000).

Here we pursue this idea in the context of a social network model (see Toivonen et al., 2009, for an overview of such models). We demonstrate that simple constraints on random network formation due to spatial embedding, limited energy, and the influence of social synergy can generate structures that exhibit key features of social networks: high clustering, right-skewed degree distribution, positive degree assortativity, and strong community structure.

The article is organized as follows. In the next section we give a brief introduction to random geometric graphs, including an energy constrained variant of this network class. Subsequently, we present the REDS model, an extension to the energy-constrained random geometric graph that allows for social synergy to mitigate the costs of maintaining inter-node relationships. The following section presents and discusses the main numerical results, demonstrating that the new model is capable of generating networks that share key properties with real-world social networks. The paper concludes with a summary of the key findings.

Social and Spatial Network Models

Most studies of complex networks, including social networks, consider relational networks where physical distances between nodes are not represented. However, most systems, including social, biological and environmental networks, are embedded in Euclidean space (see Barthélemy, 2011, for a recent review of the field). While relational social network models are important and have been studied in depth (see, e.g., Vázquez, 2003; Catanzaro et al., 2004; Toivonen et al., 2006; Kumpula et al., 2007), their spatial aspects are less well explored (but see Boguñá et al., 2004; Wong et al., 2006; Serrano et al., 2008; zu Erbach-Schoenberg et al., 2014, for some recent attempts).

The canonical spatial network model is the Random Geometric Graph (RGG). We shall use this simple model as the foundation for the work presented here. A RGG is obtained when points located in a plane are connected according to a geometric rule, e.g., connect all pairs of nodes separated by less than a threshold distance, R. There is an extensive mathematical literature on random geometric graphs, particularly in the context of continuum percolation (Dall and Christensen, 2002; Penrose, 2003; Barthélemy, 2011).

In order to generate an N-node RGG with distance threshold, R, distribute N nodes uniformly at random in the unit space, $\Omega \in \mathbb{R}^2$, and add an edge between every pair of nodes separated by a distance r < R, using the standard Euclidean metric on \mathbb{R}^2 . Furthermore, unless otherwise noted, here we shall assume that the unit space, Ω , is the square $[0,1]^2$ with

cyclic boundary conditions (i.e., a torus).

Several RGG variants exist. For example, the Manhattan distance is sometimes used to model mobility networks (Glauche et al., 2003). The general properties of these networks are very close to those employing the more common Euclidean distance, which are the ones we describe here.

The average degree, \overline{k} , of a RGG can be easily estimated as $\overline{k}=\rho V$, where $\rho=N$ is the node density, i.e., the number of nodes per unit space, and V is the neighborhood area. In this case $\overline{k}=N\pi R^2$. The degree distribution of RGGs with a sufficiently large number of nodes can be estimated by the Poisson distribution with parameter $\lambda=\overline{k}$ (Dall and Christensen, 2002).

For large N, the clustering coefficient of a RGG (i.e., the average over all individual node's clustering coefficients, Newman, 2010) tends to $1-\frac{3\sqrt{3}}{4\pi}\sim 0.5865$ for all 2-dimensional RGGs in the Euclidean space (Dall and Christensen, 2002). This important result depends on the particular construction of RGGs. The average clustering coefficient tends to the ratio of the average shared neighborhood area of two connected nodes to the whole neighborhood area. It is clear that changing the radius, R, does not alter this value.

RGGs exhibit positive assortativity, i.e., there is a positive correlation between the degree of pairs of connected nodes (Boccaletti et al., 2006). Antonioni and Tomassini (2012) demonstrate that the assortativity of any *d*-dimensional RGG tends to the value of its average clustering coefficient (a similar result was presented by Barnett et al., 2007, for spatial networks more generally). Many more properties of RGGs are derived by Penrose (2003).

Energy constrained RGGs (Antonioni et al., 2013, hereafter EC-RGGs) are an extension to the standard RGG model where each of a node's connections costs an amount of energy equivalent to its Euclidean length. In addition to the standard constraint that each edge cannot cost more than R, the total cost of an individual node's edges may not exceed some finite threshold value, E. Networks are constructed by assigning legal edges at random until no more edges can be afforded. For large E, EC-RGGs tend to become equivalent to RGGs, saturating such that all edges of length less than R are present in the graph. Where both E and R are large, complete graphs are obtained. However, where both E and R are limiting factors, EC-RGG graphs exhibit a range of clustering and (positive) assortativity values (unlike RGGs). However, neither RGGs nor EC-RGGs exhibit the skewed degree distributions and community structure that are characteristic of social networks.

The REDS Model

The REDS model builds on the RGG and EC-RGG models by including and parameterising the positive influence of shared network neighbours on the cost of maintaining relationships (see Fig. 1). The intuitions here are that (i) there is a limit to the distance over which a relationship can be

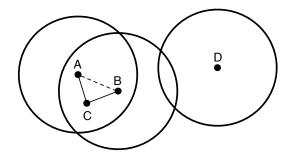

Figure 1: Nodes (dots) may become linked by edges (solid lines) only if (i) they fall within each other's social reach (circles), excluding the possibility of edges AD and BD, and (ii) they can afford to. The cost of edge AB increases with the distance between A and B, but may be reduced by the presence of any shared neighbours of A and B, e.g., C.

maintained, (ii) relationships between nodes vary in terms of cost, (iii) longer distance relationships cost proportionately more than shorter distance relationships, and (iv) relationships with individuals that are themselves connected together may be cheaper to maintain.

This last intuition is exemplified as follows. If I have two friends that know each other, in order to keep my relationship with each of them alive I don't have to physically visit or interact with each of them to the same extent that I would have to in order to maintain two unconnected friends. Direct interaction with one friend effectively involves an element of indirect interaction with friends that we share in common through gossip, chance encounters, group gatherings, etc. In more general terms, this is a local network effect that represents the potential for synergetic or catalytic interactions between the system elements.

The REDS model thus comprises four components:

- 1. **Reach**: an undirected edge, ij, between a pair of nodes, i and j, may only exist if the Euclidean distance between them, D_{ij} , is less than their "social reach", R.
- 2. Energy: each node, *i*, has a finite quantity of "social energy", *E*, that may be spent on maintaining its edges.
- 3. **D**istance: the cost, c_{ij} , of edge ij is proportionate to the Euclidean "social distance", D_{ij} , between i and j.
- 4. Synergy: the cost, c_{ij} , of edge ij varies inversely with the number of network neighbours that i and j share, k_{ij} . This effect is parameterised using $0 \le S \le 1$.

More explicitly, the cost of each edge is calculated as:

$$c_{ij} = \frac{D_{ij}}{1 + Sk_{ij}},$$

where k_{ij} , the number of neighbours shared by i and j, is the cardinality of the intersection between the set of i's neighbours and the set of j's neighbours.

Thus, when S=0 the model reduces to the energy constrained RGG model, with $c_{ij}=D_{ij}$. However, where $0 < S \le 1$, the model incorporates a local network effect that reduces the cost of edges between nodes that have network neighbours in common. Where S=0 each relationship must be maintained independently, whereas for positive S, while maintaining each relationship always involves a non-zero cost, these costs are lower for relationships that involve nodes with shared neighbours. For example, when two friends meet they may discuss or interact with common friends, reinforcing those relationships at a cost less than that of visiting or interacting with all neighbours individually.

The construction process to build an N-node REDS network with social reach R, social energy E, and social synergy S can be summarized as follows:

- 1. A population of N nodes are distributed uniformly at random in the unit square $\Omega \in \mathbb{R}^2$. Each node, i, is allocated the same initial energy, $E_i = E$.
- 2. A node i is picked uniformly at random from the population, and a second node j is chosen uniformly at random from the set of nodes for which the Euclidean distance $D_{ij} < R$.
- 3. An undirected edge between i and j is created only if both nodes have sufficient energy to afford the new set of neighbours that would result. For i, this condition is met if $E_i \geq \sum_x c_{ix}^{+ij}$, where c_{\cdot}^{+ij} denotes the cost of an edge in the updated graph including the new edge ij, and x are the neighbours of i in this updated graph. The same condition must hold for j, mutatis mutandis.
- 4. Steps 2 and 3 are repeated until no more edges can be created according to the linking rule.

The maximum cost that a node, i, may need to pay in order to maintain its k edges occurs when either S=0 (no synergy) or none of i's neighbours are connected to each other, i.e., for each neighbour, j, of i, $k_{ij}=0$. In such a case, the total cost to i is $\sum_j D_{ij}$ which is the sum of all the distances from i to its neighbours. This is appropriate, since the worst case scenario is that a node must pay to maintain each of its relationships independently.

The minimum cost that a node, i, may need to pay in order to maintain its k neighbours occurs for scenarios where S=1 and where i's neighbours form a perfect clique, i.e., for each neighbour, j, of i, $k_{ij}=k-1$. In such a case, the total cost to i is $\sum_j \frac{D_{ij}}{1+k-1} = \frac{1}{k} \sum_j D_{ij}$ which is the average distance from i to one of its k neighbours. This is appropriate, since perfect synergy (maximum S) should not reduce the cost of a set of neighbours to less than the cost of maintaining a relationship with one of them.

Notice that edges are undirected and edge costs are symmetric, with $c_{ij} = c_{ji}$. However, it may be the case that while i can afford a potential new edge, ij, the same edge is not affordable for j as a result of i and j having differing existing edge costs that result in j not having enough remaining energy. Such an edge would not be added to the network, since both of the nodes must be able to afford a new edge connecting them, Notice also that (for S > 0) as edges are added to a network, the cost of both existing network edges and potential new edges may change as a consequence of the creation of new shared neighbours. Thus, even if the number of edges in a graph increases monotonically during construction, the amount of residual energy available to individual nodes (and to the network itself) may sometimes increase (although no node ever has access to more than its initial allocation of energy E_i). Thus, unlike both RGGs and EC-RGGs. the construction of a REDS network may be path dependent.

Results

Figure 2 shows three example networks generated by the REDS model: no synergy (top), high synergy (middle), and no synergy compensated for with increased energy (bottom). All three graphs share the same value of $N=10^3$ and R=0.1, and all exhibit some clustering (the presence of triangle motifs in the network), positive assortativity (high-degree nodes tend to be directly connected to other high-degree nodes at a greater than chance frequency) and community structure (sets of nodes exist, within which pairs of nodes are more likely to be connected to each other than to nodes outside the set).

The no-synergy network (Fig. 2-Top) is sparsely connected and lacks distinctive community structure, whereas a network of equivalent energy but increased social synergy (Fig. 2-Middle) has (i) increased mean degree, because social synergy ensures that some edges become cheaper to maintain, and (ii) stronger community structure, because social synergy ensures that adding edges during network construction tends to reduce the cost of nearby edges involving the same nodes, rather than edges in general. A network with no social synergy but increased energy (Fig. 2-Bottom) is capable of achieving the same mean degree as the high-synergy network, but does not achieve its high clustering, assortativity and heterogeneous community structure.

Figure 3 presents a more comprehensive picture of how the mean degree, mean clustering and assortativity of REDS networks vary with model parameters. Each heat map evidences two sharply defined regimes in the $S \times E$ plane of the model's parameter space¹: the "saturated" regime and the "sparse" regime.

 $^{^{1}}$ We hold N and R constant since they can be thought of as defining a "scale" for the model in terms of node density, N, and the average distance between potential neighbours, 2R/3.

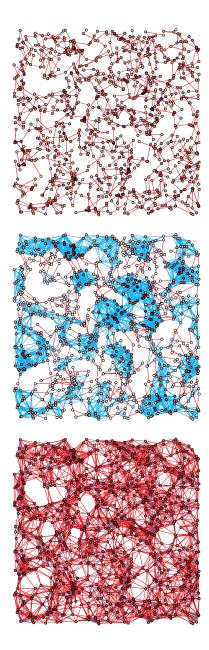

Figure 2: Example REDS networks ($N=10^3,\,R=0.1$). Red nodes have higher degree; red edges have higher cost and blue edges lower cost. $Top~(S=0,\,E=0.15)$: no synergy results in a sparse ($\overline{k}=3$) graph with modest clustering (0.1) and assortativity (0.33). $Middle~(S=1,\,E=0.15)$: maximum synergy results in a dense graph ($\overline{k}=12$) with stronger clustering (0.5) and assortativity (0.65), and evident community structure. $Bottom~(S=0,\,E=0.9)$: no synergy, but sufficient energy to match the middle graph's density ($\overline{k}=13.7$), results in lower clustering (0.34) and assortativity (0.16) and less evident community structure. (Nb. For illustrative clarity, networks were constructed on a bounded unit square, here, rather than a torus.)

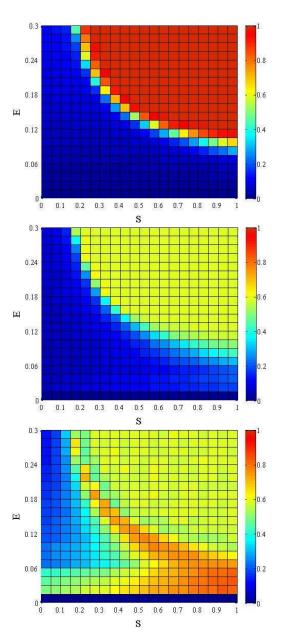

Figure 3: Mean degree (top), clustering coefficient (middle) and assortativity (bottom) for REDS networks ($N=10^4$, R=0.05). Each cell averages 10 independent networks. Mean degree is normalized w.r.t. $k_{max}=N\pi R^2$ (~ 78.54 , the mean degree for a RGG where $N=10^4$ and R=0.05). Clustering is calculated as the mean node clustering coefficient. For large E and/or S, a distinct "saturated" regime exists where degree ~ 78.54 , clustering ~ 0.5865 and assortativity also ~ 0.5865 (i.e., the values predicted for RGGs of equivalent density by Dall and Christensen, 2002; Antonioni and Tomassini, 2012). Outside this regime, degree and clustering are somewhat lower, while assortativity varies considerably with S and E. (For E=0, the empty graph obtains.)

The saturated regime is characterised by high E and high S and is associated with REDS networks that are equivalent to saturated RGGs. This regime corresponds to scenarios in which each node starts with enough energy to accumulate connections to all of the $k=N\pi R^2$ nodes that lie within its social reach. This threshold value for E is high when S=0, because each edge must be paid for independently, but it decreases rapidly as S increases, since synergy reduces the energy that must be spent on edges that close triangles.

Where synergy is minimal (S=0), the total cost incurred by a node, i, when connecting to all of the k nodes within its social reach is $\sum D_{ij} \ \forall j: D_{ij} < R$. Since the mean distance to a neighbour is just 2R/3, the boundary between the two regimes is $E=2N\pi R^3/3$ for S=0 (~ 2.61 for the scenarios plotted in Fig. 3). Where synergy is maximal (S=1), each node still requires some non-zero amount of energy in order to connect to all of the nodes within its social reach. In such a scenario, if a node, i, were able to form a perfect clique with all of the nodes within its social reach, the total cost of i's edges would be equal to $\frac{1}{k} \sum D_{ij} \ \forall j: D_{ij} < R$, i.e., the average distance to a node within its social reach, or 2R/3 (0.03 $\frac{1}{2}$ for the cases plotted in Fig. 3).

However, this value is a lower bound that cannot be reached in practice. First, during the network construction process, before a node can come to be part of minimally expensive clique it must first be part of an incomplete clique that is necessarily more expensive. Therefore, nodes must have access to more energy than is required by the lower bound calculation considered above. It is also the case that the order in which nodes accumulate edges will tend to impact on the extent to which they can achieve a maximal final degree. Second, spatial constraints ensure that a node cannot form a perfect clique with every node within its social reach since some of these nodes will be separated by a distance greater than R and therefore cannot themselves become neighbours. Consequently, for networks where S=1, the regime boundary will tend to occur at E>2R/3.

The saturated regime transitions sharply to a "sparse" regime within which REDS networks are very different from RGG networks. For very low values of E and/or S these networks become fragmented, with nodes unable to afford to maintain more than a few neighbours. However, with moderate values of S and E (below the regime threshold), we find networks that, although sparsely connected by comparison with RGGs, still exhibit significant clustering and a wide range of positive assortativity values, including values that are significantly higher than those of RGGs. This high assortativity indicates the presence of dense pockets of high-degree nodes separated by a hinterland of low-degree nodes connected together (e.g., Fig. 2-Middle).

Moreover, these sparse-regime networks exhibit degree distributions that are very different from the Poisson distributions characteristic of RGGs in the saturated regime (see Fig. 4). Sparse-regime networks tend to exhibit degree distributions that are more sharply peaked than a Poisson and (for some values of S and E) significantly more positively skewed. Interestingly, at and around the boundary between the two regimes, we see degree distributions that are a super-position of the individual distributions associated with each regime, suggesting that while some parts of the network have managed to achieve RGG-like configuration, others have not been able to do so.

More generally, it is instructive to ask: to what extent does a node's final status within the network depend on its initial location in the spatial distribution? Although the distribution of nodes is uniform random, there will necessarily be some variation in the local conditions that each node experiences. Some nodes will have access to more or less potential neighbours within their social reach, R. It might be expected that nodes that are initially disadvantaged by being located in a more sparsely populated patch of space could tend to end up with fewer neighbours in the final graph. Might this effect be responsible for the patches of densely interconnected nodes separated by "hinterland" regions of relatively sparsely connected nodes in some networks?

Figure 5 goes some way towards answering this question by plotting, for the same range of REDS networks displayed in Fig. 4, the final degree achieved by network nodes against the maximum degree that the nodes would have achieved had they been able to connect to every node within their social reach. This figure again reflects the two regimes that we have seen in previous figures. In the saturated regime, the RGG-like networks necessarily exhibit a strong identity relationship between the degree that a node achieves and the maximum degree that it could achieve given the availability of potential neighbours within its reach.

However, for networks within the sparse regime, the relationship between potential degree and actual realised degree is very different. Node degree here is obviously lower in general, but it is also not predicted by the number of potential neighbours within reach. Whether a node is advantaged or disadvantaged by the number of neighbours available at the location in which they are placed has little to do with the degree that they ultimately attain. Indeed, for moderate E and S within this regime (where degree distributions are wider due to the availability of energy and the relative cheapness of some triangle-closing edges) having an average starting location might be most beneficial (e.g., S = 0.5, E=0.09). Again, as with previous figures, we see an interesting hybrid effect at the regime boundary. For instance, where S=0.75 and E=0.09, a large sub-population of nodes exhibit a (slightly depressed) RGG-like distribution, while the remaining nodes are distributed as per a regular sparse regime network. This effect is even more pronounced for S=1 and E=0.09. Again, such scatterplots can be interpreted in terms of hybrid networks within which some spatial regions are close to achieving RGG-like configurations, but other regions are not.

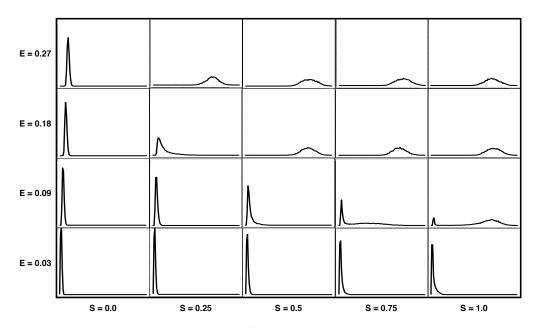

Figure 4: Degree distributions for REDS networks ($N=10^4, R=0.05$). Sub-plot x-axes represent node degree: $0 \le k \le 100$; y-axes represent the number of nodes with that degree: $0 \le p(k) \le 4000$. Two distinctive regimes exist: the "saturated" distribution is Poisson with $\lambda = \overline{k}_{max} \sim 78.54$; the "sparse" distribution is sharply peaked and can be positively skewed. At the boundary between the regimes, hybrid multi-modal distributions can be observed, e.g., for S=1.0, E=0.09.

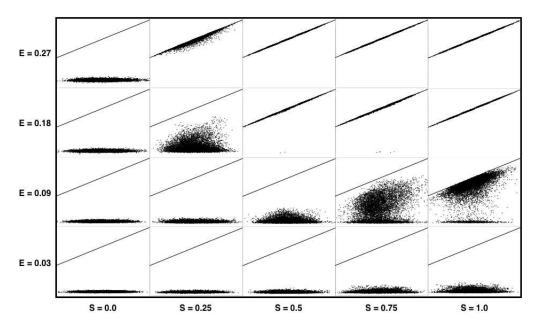

Figure 5: Scatterplots of realised degree (y) against maximum potential degree (x) for REDS networks $(N=10^4,R=0.05)$. Sub-plot x-axes represent maximum potential node degree: $50 \le n \le 110$; y-axes represent actual realised node degree: $0 \le k \le 110$. (A small quantity of jitter noise (<5%) has been added to better indicate density where many datapoints have identical locations.) Again, two distinctive regimes exist: the "saturated" distribution ranges along the line y=x (the upper bound on node degree) with maximum degree predicting realised degree; the "sparse" distribution shows little effect of potential degree on realised degree. Again, hybrid distributions can be observed at the boundary between the regimes, e.g., for S=1.0, E=0.09.

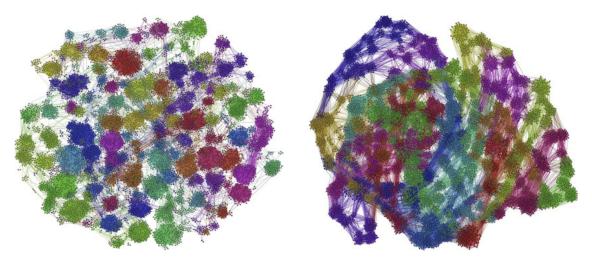

Figure 6: Community structure projections for two REDS networks with differing synergy but similar degree $(N=10^4,R=0.05,\overline{k}\sim 13.5)$. Left (S=1.0,E=0.065): High synergy results in many (49) sharply defined communities (average clustering coefficient = 0.38, modularity = 0.95). Right (S=0.1,E=0.3): Low synergy results in fewer (24) lesswell defined communities (average clustering coefficient = 0.2, modularity = 0.865). Nodes are coloured by community membership. Each layout relocates nodes to reflect their network relationships rather than their original co-ordinates. The OpenOrd algorithm was used for visual representation (Martin et al., 2011). Modularity was calculated using the fast unfolding algorithm due to Blondel et al. (2008). (Nb. For illustrative clarity, networks were constructed on a bounded unit square, here, rather than a torus.)

Figure 6 depicts two REDS networks non-spatially in order to reveal the community structure that they exhibit. Each network is projected onto the 2-d plane in such a way as to reflect its relational, rather than spatial, organisation. Modularity analysis was carried out using the algorithm due to Blondel et al. (2008). By colouring the nodes according to which community they are assigned, we can get a sense of the effect of social synergy on community structure. Whereas the high-synergy network presents a large number of distinct and well-separated communities, the low-synergy network (despite having the same average degree and same spatial distribution of nodes) presents less community structure with fewer resolved communities and more interaction between them. This is consistent with the results presented above, since in the absence of social synergy the uniform distribution of nodes tends to generate an undifferentiated blanket of connectivity, whereas in the presence of social synergy genuine community structure arises and organises in a way that is constrained by distance and energy, but tends to transcend the original spatial layout of the nodes.

Discussion

In the previous section we were able to demonstrate that the number of potential neighbours within a node's reach was not a predictor of its eventual degree for networks within the sparse regime. However, we did not demonstrate what property or properties of a node *did* predict this outcome of the network construction process.

It is likely (although yet to be confirmed) that, in the sparse regime where S>0, whether a node achieves a high or low degree during network construction is determined by the first few edges that are allocated in its locale, rather than the number of potential neighbours within its reach. Nodes that are lucky enough to be assigned edges early in the construction process will enjoy the same kind of rich-get-richer advantage that is enjoyed by nodes that arrive early during a process of preferential attachment (Barabási and Albert, 1999). While preferential attachment explicitly biases network growth in favour of well-connected nodes through its global choice mechanism, the current model achieves something similar by encouraging clique-ish sub-graphs to form around focal nodes with higher than average local clustering.

It is also likely (although yet to be confirmed) that nodes that connect initially to relatively near-by neighbours (rather than other affordable neighbours that are more distant but still within reach) are advantaged during the construction process. Expending energy on connecting with a relatively near-by node means more energy remains to be spent on a new neighbour, and also increases the chance that such a new neighbour can (afford to) close a triangle with you and your first near-by neighbour.

In order to explore this issue, and to better characterise the saturated/sparse regime boundary, it may be useful to consider a "greedy" version of the model in which, rather than picking a random affordable edge, nodes select the cheapest possible new edge.

Conclusion

In this article we have proposed an original model for the construction of social networks that are spatially embedded, constrained by limited energy, and influenced by some degree of social synergy. We started from the random geometric graph model and added three additional ingredients in order to generate networks that possess several of the statistical features exhibited by actual spatial social networks.

The main idea is to attribute a limited but equal amount of social energy to each of a set of spatially embedded nodes. Nodes can spend this resource to link to other nodes as a function of their Euclidean distance, longer links being more expensive than shorter ones, but this cost may be offset by the catalytic or synergetic effect of shared social connections. In this way we obtain networks that resemble realworld networks from the point of view of their statistical features. In particular, the generated networks have high clustering, positive degree correlation, and the presence of community structure. Within a "saturated" regime the model recovers the properties of random geometric graphs, but outside this regime there exists an interesting and varied class of networks that may exhibit degree distributions and community structure reminiscent of organic modular networks.

The model presents several possibilities for further research with the purpose of understanding more about the generic properties of networks inspired by constraints on social processes. For example, one could assume that nodes are not static in space, but move from place to place, perhaps stretching or breaking connections as they do so. This type of process may have the potential to introduce the kind of long-distance links that reduce the characteristic path length of small world networks. Furthermore, it might be reasonable to consider heterogeneity in the distribution of social energy or social reach or social synergy among the nodes. The linking process is bilateral in the present version, i.e., both partners must pay the same amount of energy to create the connection. One-way links could also be considered and the model could be extended to make it dynamical allowing for link removal as well as link formation.

Effects of Evolution on the Emergence of Scale Free Networks

Bijan Ranjbar-Sahraei¹, Daan Bloembergen^{1,3}, Haitham Bou Ammar², Karl Tuyls³ and Gerhard Weiss¹

¹Department of Knowledge Engineering, Maastricht University, The Netherlands

Abstract

The evolution of cooperation in social networks, and the emergence of these networks using simple rules of attachment, have both been studied extensively although mostly in separation. In real-world scenarios, however, these two fields are typically intertwined, where individuals' behavior affect the structural emergence of the network and vice versa. Although much progress has been made in understanding each of the aforementioned fields, many joint characteristics are still unrevealed. In this paper we propose the Simultaneous Emergence and Evolution (SEE) model, aiming at unifying the study of these two fields. The SEE model combines the continuous action prisoner's dilemma (modeling the evolution of cooperation) with preferential attachment (used to model network emergence), enabling the simultaneous study of both structural emergence and behavioral evolution of social networks. A set of empirical experiments show that the SEE model is capable of generating realistic complex networks, while at the same time allowing for the study of the impact of initial conditions on the evolution of cooperation.

Introduction

Understanding the dynamics of networked interactions is of vital importance to a wide range of research areas. For example, these dynamics play a central role in biological systems such as the human brain (Bullmore and Sporns, 2009) or molecular interaction networks within cells (Barabási and Oltvai, 2004); in large technological systems such as the word wide web (Easley and Kleinberg, 2010); in social networks such as Facebook (Backstrom et al., 2011; Ghanem et al., 2012; Ugander et al., 2011); and in economic or financial institutions such as the stock market (Chapman et al., 2012; Jackson, 2008). Recently, researchers have focused on studying the evolution of cooperation in networks of selfinterested individuals, aiming to understand how cooperative behavior can be sustained in the face of individual selfishness (Hofmann et al., 2011; Nowak and May, 1992; Santos and Pacheco, 2005; Ranjbar-Sahraei et al., 2014).

Many studies have targeted the discovery of structural properties of networks that promote cooperation. For instance, Santos and Pacheco (2005) show that cooperation has a higher chance of survival in scale-free networks; Oht-

suki et al. (2006) find a relation between the cost-benefit ratio of cooperation and the average node degree of a network that determines whether cooperation can be sustained; and Van Segbroeck et al. (2010) look at heterogeneity and clustering to find that these structural properties influence behavior on the individual rather than network-wide level. Others have focused on the role of the particular interaction model between neighboring nodes in determining the success of cooperation. For example, Hofmann et al. (2011) simulate various update rules in different network topologies and find that the evolution of cooperation is highly dependent on the combination of update mechanism and network topology. Ranjbar-Sahraei et al. (2014) propose a mathematical model, based on control theory, that allows individuals to choose their actions from a continuous range between pure defection and pure cooperation, and show that this model leads to a higher degree of cooperation than the traditional binary choice models. Control theory is also used by Bloembergen et al. (2014) aiming at ways of influencing the behaviors in social networks.

These studies have assumed the network to be fixed, looking only at the evolution of cooperation over time. In contrast, real-world social networks are not fixed, but continuously change as individuals make and break their ties (Kossinets and Watts, 2006). To this end, Zimmermann and Eguíluz (2005) and Santos et al. (2006) allow individuals to choose with whom to interact, e.g. by giving them the possibility to break ties with 'bad' neighbors and replacing them with a random new connection, and show that such a mechanism may promote cooperation. However, these works still assume a network to be in place, only modifying the connections between nodes over time.

Here, we investigate what happens when nodes are added to the network during interaction. Specifically, we start with an empty network, and add a new node at each time step. Simultaneously, the existing nodes in the network interact following the Continuous Action Iterated Prisoner's Dilemma (CAIPD) model of Ranjbar-Sahraei et al. (2014). New nodes are attached following preferential attachment. Usually, preferential attachment is assumed to follow the

²Computer and Information Science Dept., Grasp Lab, University of Pennsylvania

³Department of Computer Science, University of Liverpool, United Kingdom

Barabási-Albert model (Barabási and Albert, 1999) where links are formed to existing ones proportional to their degree. However, in many social scenarios it intuitively makes sense to look at other individuals' performance rather than their degree when determining with whom to interact - connecting with high performing individuals may give you an edge. We empirically compare both methods of preferential attachment, looking at the structure of the networks formed in detail.

This paper proceeds as follows. First, relevant background is provided on networks and game theory, and an overview of the continuous action iterated prisoner's dilemma (CAIPD) model and preferential attachment is given. These lay the foundation for the proposed Simultaneous Emergence and Evolution (SEE) model that is detailed thereafter. Finally, empirical evaluations highlight the properties of the proposed model.

Background

This section provides background knowledge needed for the remainder of the paper. Firstly, preliminaries on the theory of networks and games are given, constituting the foundation for the model of the evolution of cooperation used in this work. Hereafter, the continuous action iterated prisoners dilemma (CAIPD) is introduced. Finally, preferential attachment, used for the generation of Scale Free (SF) networks, is detailed.

Networks

Networks describe collections of entities (nodes) and the relation between them (edges). Formally, a network can be represented by a graph $\mathbb{G} = (\mathcal{V}, \mathcal{W})$ consisting of a nonempty set of nodes (or vertices) $\mathcal{V} = \{v_1, \dots, v_N\}$ and an $N \times N$ adjacency matrix $\mathcal{W} = [w_{ij}]$ where non-zero entries w_{ij} indicate the (possibly weighted) connection from v_i to v_i . If \mathcal{W} is symmetrical, such that $w_{ij} = w_{ji}$ for all i, j, the graph is said to be undirected, meaning that the connection from node v_i to v_i is equal to the connection from node v_i to v_i . In social networks, for example, one might argue that friendship is usually mutual and hence undirected. This is the approach followed in this work. In general however this need not be the case, in which case the graph is said to be directed, and W asymmetrical. The neighborhood, \mathbb{N} , of a node v_i is defined as the set of nodes it is directly connected to, i.e. $\mathbb{N}(v_i) = \bigcup_j v_j : w_{ij} > 0$. The node's degree $\deg[v_i]$ is given by the cardinality of its neighborhood.

Several types of networks have been proposed that capture the structural properties found in large social, technological or biological networks, two well-known examples being the small-world and scale-free models. The *small-world* model exhibits short average path lengths between nodes and high clustering, two features often found in real-world networks (Watts and Strogatz, 1998). Another model is the *scale-free* network, characterised by a heavy-tailed degree distri-

bution following a power law (Barabási and Albert, 1999). In such networks the majority of nodes will have a small degree while simultaneously there will be relatively many nodes with very large degree, the latter being the hubs or connectors of the network. For a detailed description of networks and their properties, the interested reader is referred to Jackson (2008).

Game Theory

Game theory models strategic interactions in the form of games (Gibbons, 1992). Each player has a set of actions, and a preference over the joint action space that is captured by the received payoffs. The goal for each player is to come up with a strategy (a probability distribution over its actions) that maximizes his expected payoff in the game. A strategy that maximizes the payoff given fixed strategies for all opponents is called a best response to those strategies. The players are thought of as individually rational, in the sense that each player purely tries to maximize his own payoff, and assumes the others are doing likewise. However, this reasoning might not always lead to a beneficial outcome for everyone, and might even be detrimental to all players in the game. Often, there is tension between individual rationality on the one hand, and social welfare on the other.

This archetypal dilemma is aptly captured by the Prisoner's Dilemma (Axelrod and Hamilton, 1981). In this one-shot interaction, players simultaneously choose between either cooperation or defection, after which payoffs are distributed based on their joint action. Cooperation is costly, however cooperators distribute benefits among the other players. Defectors do not pay a cost, but do receive benefits from cooperators as well. In this game, defection (freeriding) is a best response against any opponent strategy, and therefore individually rational players can be expected to defect. However, if all players would cooperate their distributed benefits would outweigh the cost of cooperation, and hence all players would be strictly better off. Herein lies the dilemma.

In this work the players are nodes in the network, repeatedly playing a game with their neighbors. The players have no knowledge of the underlying game, however this repeated interaction allows for adaptation, i.e. to learn a better strategy over time based on the payoff received. The game used in this paper is a generalization of the classical Prisoner's Dilemma, in that the players can have a continuous strategy defining their level of cooperation rather than a binary choice, and payoffs are calculated accordingly. The dilemma, however, remains.

Continuous Action Iterated Prisoner's Dilemma

The continuous action iterated prisoner's dilemma (CAIPD) is a mathematical model of the evolution of cooperation on complex social networks, proposed in Ranjbar-Sahraei et al. (2014). The model describes how the individuals in the net-

work, placed on the nodes, interact with their neighbors according to the aforementioned prisoner's dilemma. Cooperators incur a cost c for each interaction, while their neighbor receives a benefit b with b>c. Defectors free-ride, in the sense that they do not pay costs while still receiving benefits from cooperative neighbors.

Formally, in CAIPD the individuals in a network are represented by N vertices $v_i \in \mathcal{V}$ for $i = \{1, ..., N\}$ on a weighted graph $\mathbb{G} = (\mathcal{V}, \mathcal{W})$. The characteristics of the graph $\mathbb G$ are described by the symmetrically weighted $N \times N$ adjacency matrix $W = [w_{ij}]$. Namely, the connections between the i^{th} and j^{th} individual are denoted by $w_{ij} \in \{0, 1\}$ with all $w_{ii} = 0$. The latter prevent individuals from selfinteraction. In contrast to other existing models, CAIPD allows individuals to choose their level of cooperation from a continuous range between pure cooperation and pure defection, rather than a binary choice between those. This choice is captured by the individuals' state variable $x_i \in [0,1]$. A value of $x_i = 0$ corresponds to pure defection while $x_i = 1$ represents pure cooperation; however x can take on any arbitrary value between those extremes. Extending the prisoner's dilemma to account for this continuous nature of cooperation, a player pays a cost cx_i while the opponent receives a benefit bx_i , again with b > c. This way a defector (i.e., $x_i = 0$) pays no cost and distributes no benefits. Then, the fitness of player i can be calculated as:

$$f_i = -\operatorname{deg}[v_i]cx_i + b\sum_{j=1}^{N} w_{ij}x_j \tag{1}$$

where $\deg[v_i]$ denotes the number of neighbors of the individual v_i . Each player observes how well their neighbors are doing, and will then take over one of their neighbors' strategies with some probability based on their respective fitness difference. In particular, player i adopts the strategy of neighbor j with probability

$$p_{ij} = w_{ij} \cdot \operatorname{sigmoid}(\beta(f_i - f_i)) \tag{2}$$

where $\operatorname{sigmoid}(x) = \frac{1}{1 + \exp(-x)}$, and β is a parameter varying the opponents' influence on individual i.

A network with a state x and topology \mathbb{G} is defined as $\mathbb{G}_x = (\mathbb{G}, x)$ with $x = [x_1, x_2, \dots, x_N]^\mathsf{T}$ representing the state of each node in the network. Such a network \mathbb{G}_x can then be regarded as a dynamical system, where x evolves with respect to time. This evolution depends on a nonlinear mapping

$$\dot{\boldsymbol{x}} = [h_1(\boldsymbol{x}), \dots, h_N(\boldsymbol{x})]^\mathsf{T}. \tag{3}$$

Specifically, the dynamics of the i^{th} player are described by

$$h_i(\mathbf{x}) = \frac{1}{\deg[v_i]} \left[\sum_{j=1}^{N} p_{ij} (x_j(t) - x_i(t)) \right]$$
 (4)

where $\deg[v_i]$ denotes the number of neighbors of player i (i.e., the degree of node v_i); x_i and x_j denote the current cooperation level of players i and j, respectively; and p_{ij} represents the probability with which player i adopts the strategy of player j, as defined in Equation 2. For a detailed description of the CAIPD model, the interested reader is referred to Ranjbar-Sahraei et al. (2014).

The CAIPD model is more general than other existing models, in that is can be used to model the evolution of cooperation on arbitrary complex social networks. Moreover, the continuous nature of the model, allowing for a degree of cooperation rather than a binary choice, is better suited to model many real-world problems (Killingback and Doebeli, 2002). Finally, the deterministic nature of the mathematical model makes it computationally less complex, allowing to study a wider range of scenarios. For these reasons, we adopt this model in the current paper as well.

Preferential Attachment

The preferential attachment model was proposed by Barabási and Albert to explain the power-law degree distribution that is present in many complex real-world networks (Barabási and Albert, 1999). This model is based on the assumption that, in many social settings, the chance of making new connections grows proportionally with the number of connections that you already have (also known as the rich-get-richer phenomenon). The Barabási-Albert model simulates this by growing the network over time, adding one new node at a time, and linking it to a fixed number of existing nodes, these being chosen proportionally to their current degree. Specifically, starting from an initial network of m_0 nodes, at every time step one new node is added to the network. The new node forms $m < |m_0|$ connections to existing nodes, where the probability p_i that the new node connects to existing node v_i is proportional to its degree:

$$p_i = \frac{\deg[v_i]}{\sum_j \deg[v_j]}.$$
 (5)

Preferential attachment generates a long-tailed degree distribution following a *power-law*:

$$P(k) \sim k^{-\alpha}$$

with k denoting the degree of the nodes. The power-law exponent for the Barabási-Albert model is $\alpha=3$; in comparison, many real-works complex networks have been shown to lie in the range $2\leq\alpha\leq4$ (Barabási and Albert, 1999; Newman, 2005).

It is worth noting that although the Barabási-Albert model is a well known model for generating scale-free graphs, individual properties of the nodes other than their degree are typically not taken into account. In real world scenarios, however, both structural as well as behavioral properties affect the preferential attachment process. For instance, in a

co-authorship network, new authors may indeed have a tendency to team up with existing authors that already worked together with many others (i.e., high degree nodes, a structural property), but will also consider paper quality, number of citations, etcetera (i.e., individual behavioral properties).

In this work, we adapt the preferential attachment model of network growth to take behavioral properties into account when forming new links, where the behavior itself follows the dynamics of the CAIPD model. This approach of Simultaneous Emergence and Evolution (SEE) is detailed next.

Simultaneous Emergence and Evolution

Aiming at a unification, the Simultaneous Emergence and Evolution (SEE) model incorporates two evolutionary procedures. The first is concerned with the evolution of behaviors in the network, which follows from the CAIPD model. The second deals with the construction of the network itself. Here, preferential attachment is used. Contrary to previous works, however, the links that each new individual forms with existing nodes depend on the current fitness of those nodes under the CAIPD dynamics, rather than on their degree. Next, an in-depth description of the SEE algorithm is presented.

The SEE Algorithm

Starting from m initially connected individuals, new nodes are added one at a time. The initial state of these m nodes, as well as of each new node, are set randomly to either pure defection or pure cooperation with equal probability. Each new node is connected to m existing ones with a probability proportional to the fitness of the existing nodes, computed according to Equation 1. The connection probability p_i (i.e., the probability that a new node is connected to i) is defined as

$$p_i = \frac{f_i}{\sum_j f_j} \tag{6}$$

where f_i is the fitness of node i and the sum runs over all N pre-existing nodes $j=1,2,\ldots,N$. Therefore, nodes with high fitness tend to quickly accumulate more neighbors, while nodes with low fitness are unlikely to be chosen as the connector for a new node. An upper limit size of $N_{\rm max}$ is defined. This ensures that the network halts its expansion after reaching size $N_{\rm max}$.

In parallel to the structural emergence of the network, the CAIPD model is used to evolve the individual behaviors of the existing nodes. At each iteration, the adjacency matrix \mathcal{W} is updated. Fitnesses are then computed according to Equation 1. These new fitness values are then used to update the state of each node, and therefore of the network as a whole, using the dynamical model of Equations 3 and 4. This is in practice performed with an adequately small step size. The SEE model allows to vary the update rates of both evolutionary processes independently. For example, the behavior of the individual nodes might evolve faster or slower

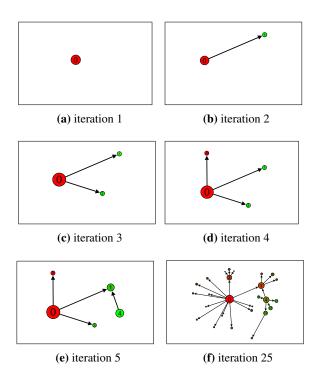

Figure 1: Emergence and evolution of a network according to the SEE model. Node size reflects individual's fitness and its color denotes the state (red for defection to green for cooperation). The direction of arrows shows how individuals influence each other.

than the rate at which new nodes are added. This ratio between the update rate of the behavior and the update rate of the network is defined by $R_{\rm Evo}$, such that when at each time step k a new node is added, the CAIPD model progresses $R_{\rm Evo}$ steps.

Illustration of SEE for a Sample Network

In this section an illustration of the SEE model on a sample network is presented. Initially, there is just one node with pure defection state $x_0=0$, as depicted in Figure 1(a). At the second iteration, Figure 1(b), a cooperating individual is entering the environment (i.e. individual 1), and gets attached to the defector (i.e., individual 0). At this stage, the defector acquires some benefits from the cooperator, while imposing a cost on the cooperator. This results in a higher fitness for the defector than the cooperator (depicted using the node size in the figure).

For further illustration, Figures 1(c)-1(e) show the attachment of three more individuals with defecting or cooperating states (chosen randomly) after joining the network. In parallel to this network emergence, individuals influence each other as described by the CAIPD model, resulting in a simultaneous evolution of their behavior. Figure 1(f) shows the structure and behavioral state of the network after the 25^{th} iteration.

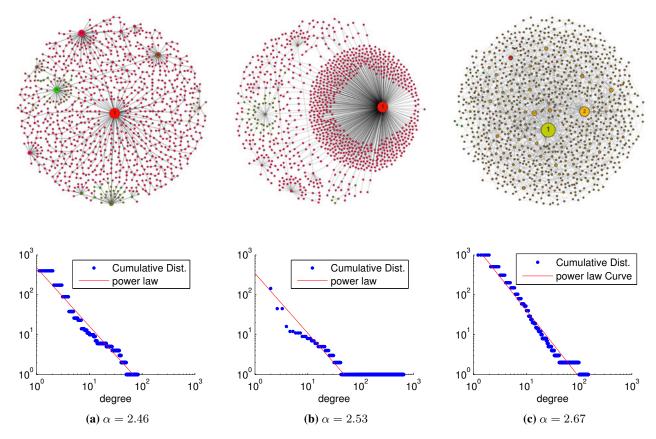

Figure 2: Sample network topologies generated by the SEE model (a) and (b) for m=1 and (c) for m=2, after 1000 iterations. The state and degree of the individuals are denoted by the color (red for pure defection to green for pure cooperation) and size of the nodes. The cumulative degree distribution of each network, shown as blue dots, shows how close this network follows a power law curve, shown as red line, with exponent α .

Experiments and Results

In this section we first illustrate sample networks generated using the proposed SEE model, and show the scale-free characteristics that emerge. Hereafter, the cumulative degree distribution of 8000 different networks generated for 8 different settings of the SEE model will be studied in detail by computing the power law exponent in these networks. Finally, the evolution of cooperation resulting from the proposed SEE model is compared to the standard Barabási-Albert model of preferential attachment. In all experiments, the upper limit for network size is set to $N_{max}=1000$. The number of links added for each new individual, m, is set to either 1 or 2 (indicated where applicable). In the CAIPD model the step size is 0.1; b=4, c=1 and $\beta=1$.

Sample Networks Generated by the SEE Model

Consider an evolution ratio $R_{\rm Evo}$ of 1 in a network that initiates from a single individual which is set initially to either pure defection or pure cooperation. When applying the SEE model, various different network structures can be expected to emerge, as there is stochasticity involved in both initial-

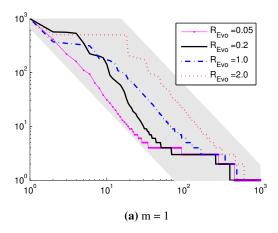

ization of the nodes' states and their attachment. Three samples of such networks are illustrated in the top portion of Figures 2(a)-(c).

In order to study whether the networks generated by the SEE model follow a power law degree distribution, the cumulative degree distribution, i.e., the number of nodes with degree greater than or equal to k, of the sample networks in Figures 2(a)-(c) are shown on a log-log scale¹. The results indeed show a power-law degree distribution with exponent close to $\alpha=2.5$ for the sample networks in Figure 2. Next, we study the average cumulative degree distribution of networks generated by the SEE model in more detail.

Degree Distribution in the SEE Model

In this section, we provide an empirical study on a large number of different networks generated using the proposed SEE model. We analyse different settings for $R_{\rm Evo}$, ranging from 0.05 (slow evolution) to 2 (fast evolution). Figures 3(a)

¹The cumulative distribution of a power law distribution is also power law but with an exponent $\alpha-1$, i.e., $\int cx^{-\alpha}=\frac{c}{1-c}x^{-(\alpha-1)}$, where c is the power law coefficient

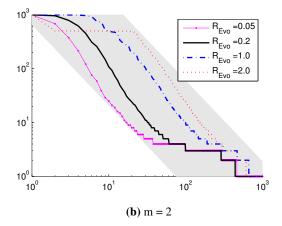

Figure 3: Cumulative Degree distribution of nodes for different evolution rates. The gray region contains the power law distributions corresponding to the scale free networks with exponent $\alpha=2.5$ and different coefficients of the power law.

and (b) show the average cumulative degree distribution of these networks for m=1 and m=2, respectively. For each combination of settings, the SEE model is run 1000 times, with initial nodes randomly set to either cooperation or defection, and the results are averaged.

It can be observed from Figures 3(a) and (b) that the networks that emerged using the SEE model, on average, largely follow a power law degree distribution with exponent close to $\alpha=2.5$. When evolution is slow (i.e., $R_{\rm Evo}\to 0$) the power law is less clearly present, in particular towards the high end of the degree distribution. A possible explanation is that, as the CAIPD evolution slows down, the fitness of the nodes gets updates less frequently as there are fewer interactions. Hence, having more neighbors does not immediately translate to a potential higher fitness.

To get a more detailed insight, the distribution of the exponent of power law distribution that is fit to the constructed networks is illustrated in Figures 4(a)-(d) and 4(e)-(h) for

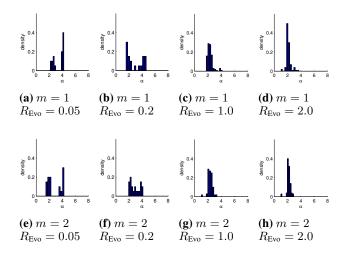

Figure 4: Distribution of the power law exponent for various evolution ratios in the SEE model.

m=1 and m=2, respectively. These figures show that the SEE networks with slow evolution rates exhibit power law degree distribution with exponents $1<\alpha<5$ (i.e., some of the networks fall outside the range of typical real-world complex networks). Increasing the evolution ratio shrinks the range of α values that are observed and centers their distribution around $\alpha=2.5$, yielding realistic scale-free networks. Moreover, it is interesting to note that a bifurcation seems to take place when $R_{\rm Evo}$ decreases (in Figures 4(a), (b) and (e)): the distribution of power law exponents splits into two parts with their mass centered around 2 and 4. This phenomenon warrants a closer inspection in future work.

SEE model vs. Barabási-Albert model

In the previous section the scale-free characteristic of the SEE model was studied and it was shown that the degree distribution of these networks follows a power law degree distribution with $\alpha \approx 2.5$. In this section we study the influence of the SEE model on the evolution of behavior in the network. We compare the proposed SEE model, which uses preferential attachment based on fitness (see Equation 6), with the standard Barábasi-Albert model that uses the degree (see Equation 5). For all experiments, $N_{\rm MAX}=1000$, and the evolution ratio $R_{\rm Evo}$ is set to 1.

Figures 5(a) and (b) show the evolution of cooperation under the SEE model, specifically the figures show the final cooperation level in the network depending on whether the initial nodes where either defectors or cooperators. Similarly, Figures 5(c) and (d) show the same results when the Barábasi-Albert (B-A) model is used for the preferential attachment. It is clear from these figures that the final cooperation level in the network greatly depends on the initial state of the first individuals. When the initial nodes are cooperators, the network tends to cooperate to a large (> 0.5) degree, whereas the situation reverses when the initial nodes

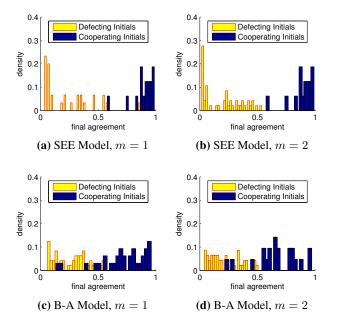

Figure 5: Final degree of cooperation as a function of the initial members' state in the SEE model in (a) and (b) and the Barábasi-Albert (B-A) model in (c) and (d). The colors indicate the state of the initial members: blue for cooperators, and yellow for defectors.

are defectors. This effect is most clear under the SEE model, where a large fraction of the networks eventually reaches either a high (≈ 1) or low (≈ 0) degree of cooperation. When preferential attachment according to Barábasi-Albert is used, this effect is less strong. Here we observe a broad mix of final cooperation levels; moreover the divide between initial cooperators and initial defectors is less clear.

Clearly, the above results demonstrate that final agreements depend on the initial state of the first individuals in the network. This phenomenon is manifested in both the SEE and the Barábasi-Albert model. Having proposed a generalized and formal framework for analysing evolution of cooperation and network emergence, this aspect constitutes a major direction in our future work, where SEE can be used to acquire analytical conclusions describing the effects of such a dependence.

Conclusions

The recent interest to study social networks and their behavior has led to many studies, which can roughly be divided in two streams. The first stream has studied the emergence of these networks, and has in particular tried to find generative models that can explain certain structural properties of real-world complex networks, such as a scale-free degree distribution. The second stream of research has focussed on the evolution of behavior on such networks, when the nodes represent individuals that interact according to some rules. Most notably, interest has been in the evolution of coopera-

tion in social networks, aiming to identify properties of both the network and the interactions that sustain cooperation.

This paper aims to unify these two streams, by studying the simultaneous evolution of behavior on a social network, and the structural emergence of the network itself. The Simultaneous Emergence and Evolution (SEE) model proposed in this paper combines a modified version of preferential attachment, used to generate scale-free networks, with the continuous action iterated prisoner's dilemma (CAIPD) model, describing the evolution of cooperation. Using the proposed model, a number of different networks, emerging from different initial conditions, have been studied. It has been shown that the SEE model yields realistic scale-free networks, despite the fact that the preferential attachment is based on individual's fitness rather than degree.

Moreover, results show that that both structural emergence and behavioral evolution are intertwined, mutually influencing each other, and should therefore be studied in tandem. Aiming at a better understanding of such phenomena, the SEE model provides a fundamental and general framework that allows the analysis of these processes as they coevolve.

An interesting direction for future work is to include the possibility of rewiring as well in the SEE model, whereby existing nodes may break or create links at any time.

Abstract

Previous work has proposed that computational modelling of social systems is composed of two primary streams of research: systems sociology, which is focused on the generation of social theory; and social simulation, which focuses on the study of real-world social systems. Here we argue that the social simulation stream stands to benefit from recent methodological and theoretical advances in demography. Demography has long been an empirically focused discipline focused primarily on mathematical modelling; however, agentbased simulation have proven influential of late as demographers seek to link individual-level behaviours to macro-level patterns. Here we characterise this shift as a move toward system-based modelling, a paradigm in which the scientific object of interest is neither the individual nor the population, but rather the interactions between them. We first describe the four successive paradigms of demography: the period, cohort, event-history and multilevel perspectives. Then we examine how system-based modelling can assist demographers with several major challenges: overcoming complexity in social research; reducing uncertainty; and enhancing theoretical foundations. We propose that this new paradigm can enhance the broader study of populations via social simulation.

Introduction

Understanding the complex and multi-layered processes at play in social systems is far from a simple task, and in recent years research efforts have focused on studying these systems using computer simulation. Taking inspiration from Alife and related areas of complex systems science, the field of *social simulation* has taken shape as a discipline devoted to the study of social systems as complex, non-linear systems composed of interacting agents.

Social simulation has grown steadily over the last decade as social scientists grow increasingly attracted to the idea of representing the complexities of the social realm using simulation (Billari and Prskawetz, 2003). However, questions remain regarding how to best utilise these tools in different contexts. Social simulation offers tremendous flexibility and provides scope for experimentation beyond simple prediction (Epstein, 2008), but what methodological frameworks can guide us in our investigations? Can complex systems

simulation approaches ever be closely linked with traditional empirically-focused social science methods?

Systems Sociology vs. Social Simulation

Previous work has examined the core questions of social simulation in-depth using several case studies as exemplars of different simulation research programmes (Silverman and Bryden, 2007). This work proposed that what we refer to as social simulation can be more accurately represented as two separate streams of research: *systems sociology* and *social simulation*.

Systems sociology encompasses the drive to develop stronger social theories regarding the development and evolution of societies. The use of simulation allows system sociologists to investigate abstract social systems in an effort to understand the core communicative processes that lead to higher-level social complexity; this instantiates the kind of investigations spearheaded by sociological theorists like Niklas Luhmann (1984).

In contrast, social simulation uses computational methods to examine specific elements of social systems, frequently based on real-world examples such as residential segregation (Schelling, 1978), or social care in ageing populations (Silverman et al., 2013). This approach benefits from a closer connection to social phenomena for which usable data is actually available, which can allow for easier validation of simulation results. However, parameterising simulations using the available data is still difficult and is not a straightforward process.

We propose that developing a consistent methodological framework for social simulation is a difficult but necessary task. Simulation approaches allow the modeller to investigate the link between micro-level behaviour and macro-level patterns, which is of great interest to social scientists. In order to further our methodological ambitions, we suggest that social simulation researchers take on board insights from the field of demography, where recent developments have indicated a shift toward a systems-level take on social phenomena that can inform and enhance social simulation efforts.

Examining Demography

Demography as a research field has existed for over 350 years, and during that time has advanced through several successive paradigmatic changes. From the early 'political arithmetics' of Graunt (1662) to current multilevel methods (Courgeau and Franck, 2007), demography has developed increasingly sophisticated means for the examination of population data. The recent popularity of agent-based approaches has prompted a shift in focus toward individual behaviours and interactions and away from strictly population-level insights (Burch, 2003b; Silverman et al., 2011). In this section we will outline the developments in demography over the last three and a half centuries and provide a summary of the primary paradigm shifts that have taken place.

In this discussion we will use a different definition of the word 'paradigm' than those developed by Kuhn (1962). Instead we take inspiration from Granger (1994) and define paradigms as a means to describe the relationship between an observed phenomena and the scientific object. In the case of demography, the scientific object is primarily population-level change – but as we shall see, recent developments indicate a shift in this fundamental perspective.

Courgeau and Franck (2007) identify four such paradigms in demography: cross-sectional (period), longitudinal (cohort), event history and multilevel. Each of these paradigms expands upon and addresses weaknesses of previous paradigms, but we must emphasise that the demography displays *cumulativity* in that new paradigms enhance new avenues of enquiry but do not replace or eliminate previous paradigms. This is similar to the cumulativity we see in other disciplines, such as physics, in which Einstein's relativity addresses weaknesses in Newton's classical mechanics, but nevertheless classical mechanics remains a more than sufficient tool for a great variety of problems in physics.

We note that this perspective on cumulativity can be seen as a departure from Kuhn, who argued that we should "take it for granted that the differences between successive paradigms are both necessary and irreconcilable" (1970). However, following on from Courgeau (2010), we posit that the knowledge generated by successive paradigms displays a non-linear cumulativity. Agazzi has argued that scientific theories focus on a small set of objects, some of which are referential and can differ between theories in the same discipline, while others are contextual and relate to the core concepts which can remain invariant between theories and therefore allow for theory comparison. Agazzi then moves beyond Kuhn and suggests that "scientific progress does not consist in a purely logical relationship between theories, and moreover it is not linear.... and may even be interpreted as an accumulation of truth" (1985).

Within demography, we will see through our historical analysis that the four successive paradigms each surpass certain shortcomings of the previous, and yet these previous paradigms are still in active use. This is because demographers using these different methodologies continue to operate in the same context, even while the perceived *relationships* between demographic events of interest change significantly from one paradigm to another. This suggests that demographic paradigms do not eliminate previous approaches but instead display a non-linear cumulativity of knowledge as new theories sit alongside one another in the broader context (Courgeau, 2010).

Next we will outline the history and structure of demography, and then we will make our case for a fifth paradigm: *system-based modelling*, which is focused on interactions within population systems.

Paradigms in Demography

Demography has its origins in the work of Graunt (1662), who is considered to be the first to apply the scientific method to the study of human populations. Graunt was able to abstract away the concepts of mortality, fertility and morbidity from individuals, and study these as objects of scientific scrutiny in and of themselves. He also connected studies of probability with these examinations of populations, leading to the first studies of events happening to statistical individuals as defined by Courgeau (2012). We characterise these early investigations, and indeed most of the following 200 years of demography, as part of the cross-sectional paradigm, in which population-level events are observed and measured according to historical time. As suggested by Courgeau (2007), we see the cross-sectional paradigm defines the social facts of a given period as existing independently of the individuals affected.

The next paradigm, *longitudinal analysis*, came about through American researchers including Ryder (1951) and was eventually formalised by Henry (1959). Under this paradigm the demographer studies the occurrence of a single event during the life of a cohort (a group of individuals experiencing a particular event during a particular stretch of time). However, this approach requires that this cohort be homogenous and the phenomenon under study must be independent (Courgeau, 2007). The restrictive nature of this approach meant that a new paradigm was soon required in order to allow the study of heterogeneous cohorts and to allow for dependencies between phenomena of interest.

That paradigm soon manifested in the form of the *eventhistory analysis* approach, pioneered by Aalen (1975) following the introduction of general theories of stochastic processes. In this paradigm individuals are seen to follow complex trajectories that depend upon previous events and information they have acquired in the past (Courgeau, 2007). This approach necessitates the use of detailed surveys which can collect data on events and characteristics on an individual level. However, this approach requires significant assumptions when applied to the study of population change; chief among these is the assumption that all individuals are assumed to follow the same random process, the parameters

No.	Paradigm	Period	Key Focus			
1	Period (cross-sectional)	1662-	Population-level phenomena, observed and measured according			
			to historical time			
2	Cohort (longitudinal)	1950s-	Population-level phenomena, observed and measured along the			
			lifetime of individual cohorts			
3	Event History	1980s-	Individual-level phenomena, observed and measured according			
			to individual time			
4	Multilevel	1980s-	Individual, population, and interim-level phenomena, observed			
			and measured from multiple perspectives			
5	System-based	2000s-	Interactions between population systems of individuals, groups			
			and institutions			

Table 1: A summary of the four previous paradigms of demography

of which are estimated from the statistical sample of individuals.

In order to introduce different types of groupings of individuals and allow for the influence of a broader social context, demographers turned to the fourth paradigm: *multilevel analysis*. This context could include socio-economic groupings, social networks, etc. The multilevel approach addresses weaknesses of the event-history approach by allowing for individual behaviour to be constrained by external factors (Courgeau, 2007). While these advantages are significant, multilevel analyses still do not allow for feedback effects (i.e., influences on higher-level behaviour from individual actions), and we shall see how our proposed fifth paradigm addresses these shortcomings.

While we can see a clear progression in demography toward the examination of increasingly complex relationships between social facts at the individual and population levels, each of these paradigms remains in use in certain contexts. Indeed, cross-sectional analyses remain relevant for certain investigations in demography, and this is likely to remain the case for the foreseeable future. In order to examine the complex interactions and feedbacks between the individual level and the population level, however, we need another advancement in methodology. In the next section we outline some of the most pressing challenges facing demography, which will lead to our proposal for the fifth demographic paradigm.

Epistemological Challenges in Demography

The development of demography in recent decades has been closely tied to debates around epistemological challenges. The advent of the multilevel approach, for example, was a product of extensive discussion amongst demographers regarding the examination of multiple levels of analysis in population science. Currently demographers are taking on the issues of uncertainty and complexity.

Demographic changes are inherently uncertain, as with any other aspect of social systems, although demography appears less susceptible to uncertainty in some respects than some related disciplines (e.g., economics). Demographers contend that this is due to the strong empirical slant of the field, and to the power of the statistical relationships which provide the foundations for much of the research in this area (Xie, 2000). Of course some fundamental aspects of population change are considered more uncertain than others; migration, for example, is thought to be much more uncertain than mortality, given that the former can be strongly affected by a number of factors which can change rapidly, such as economic conditions or legislative changes (Xie, 2000). The open and frequent discussion of uncertainty in demography has led to the 'return of the variance' to demography, which has been of great importance to work within all four paradigms described in the previous section (Courgeau, 2012).

The complexity of social phenomena also increases the uncertainty inherent in demographic change, and so additional methodological innovation is required to address these challenges. While significant debate on complexity in demography has been ongoing (Silverman et al., 2011), there is relatively limited evidence available on the performance of demographic models at varying levels of complexity. When looking at predictive applications, opting for simple models that describe uncertainty in detail may be most appropriate (Bijak, 2010). Prediction is far from the only goal in demography, however – as with social simulation (Epstein, 2008) – so other approaches are still required.

These realisations have led to a move toward instantiating demography as a 'model-based science', as we have seen in population biology (Godfrey-Smith, 2006). Some comparisons between modelling in population biology and in artificial life have outlined how these biological applications have important lessons for modellers in other fields (Bullock and Silverman, 2008). However, models of social reality add additional layers of complexity for the modeller; in particular, formalising the relationships between different levels of social phenomena is far from straightforward (Kluver et al., 2003).

Addressing Uncertainty

As these investigations of demographic methodology have progressed, demographers have acknowledged that model uncertainty must be addressed, given the emphasis on formal statistical models in demographic applications. If models themselves are to be acknowledged as sources of additional uncertainty, then the most relevant approach to describing these uncertainties is via Bayesian statistical inference and epistemic probability (see Courgeau, 2012; Raftery, 1995, for discussion). Within this category there are varied approaches to describing model error, from selecting models out of several competing possibilities and related model averaging (Raftery, 1995), to including additional terms for model discrepancy within the modelling process itself (Kennedy and O'Hagan, 2001; O'Hagan, 2006). In addition, Bayesian statistics can allow the modeller to include subjective opinion during the statistical inference process (see, e.g. Bijak, 2010).

Further, Bayesian statistics provides a way to reconcile model-based and empirical approaches by returning to empiricism at a different level of analysis. Computational models, regardless of their structure or complexity, have input parameters and outputs of interest. Various statistical techniques allow for statistical analysis of this mapping, including Bayesian melding (Poole and Raftery, 2000), and Gaussian process emulators (Kennedy and O'Hagan, 2001); for examples of the latter approach in demographic applications, see Bijak et al. (2013) and Silverman et al. (2013). These methods help to alleviate one of the major shortcomings of complex computational models – their relative opacity compared to formal mathematical models – by allowing for an in-depth analysis of the input-output mapping using a formal statistical framework.

Finally, these uncertainty evaluations can be validated by examining various error measures and at empirical frequencies related to predictive intervals with different nominal probabilities. These techniques have been applied in several demographic studies to date, including Bijak (2010), Clark et al. (2012), and Raftery et al. (2012). Quality of calibration can be assessed using scoring rules, as in Gneiting and Raftery (2007).

New Modelling Approaches for Demography

This growing interest in new modelling methodologies for demography has led to a number of proposals in the literature, many of which have been inspired by agent-based computational approaches (see Billari and Prskawetz, 2003; Bijak et al., 2013; Silverman et al., 2013). Demographers have expressed enthusiasm about the possible ramifications for improving the theoretical foundations of demography (Chattoe, 2003; Burch, 2003a), and some recent work has focused explicitly on developing comprehensive social theories based on demographic foundations (Lutz, 2013). Others have pointed out the benefits of using agent-based models

to avoid the over-dependence on increasingly detailed and expensive survey data at the expense of the realism of the explanations offered (Silverman et al., 2011).

The perceived utility of agent-based approaches for explanatory aims has been a significant attraction for demographers (Burch, 2003b; Silverman et al., 2011). Agent-based models are designed to represent the impact of individual behaviours on macro-level patterns and effects. Thus, we contend that agent-based models belong to a broader class of *system-based models*, which are models specifically intended to represent systems composed of interacting elements. In the demographic context, any human population is in fact composed of multiple interacting levels of complexity: individuals, social groups, institutions, etc., any and all of which are suitably complex for in-depth investigation in their own right.

By acknowledging this fundamental aspect of the social realm, demography can continue to shift toward model-based science by making those interactions between different elements of the population an explicit *object of scientific interest*. This then instantiates system-based models in demography as a method for representing interacting, complex behaviours and investigating how these interactions shape demographic change. Re-casting demographic model-building in this way has clear ramifications for future efforts to build stronger theories regarding population change.

This is not to say that system-based approaches are the only option – and indeed, numerous demographic problems will still be addressed perfectly adequately with previous, well-established modelling paradigms. Further, system-based models are somewhat dependent on the presence of sensible theories regarding social systems, and such theories are very difficult to formalise (Kluver et al., 2003; Moss and Edmonds, 2005). A possible way out of this difficulty may be to reconnect system-based approaches to a classical scientific research programme which promotes a functional-mechanistic analysis of populations (Franck, 2002a).

System-Based Modelling

Bringing all of these elements together, we propose that demography is in need of a fifth paradigm, one which maximises the strengths of empirical demographic research as well as the flexibility of simulation methods. While agent-based methods have limitations of their own, as outlined above, this new paradigm integrating these methods into the empirical and inductive research programme of demography may allow us to surpass these difficulties. To do so, we must shift toward a new scientific object in demography: interactions.

Therefore we have proposed a fifth, new paradigm for demography: *system-based modelling*. This approach is based on a functional-mechanistic research programme, which we discuss in more detail in the next section. Agent-based

modelling is of course a possible methodology for implementing a system-based modelling approach, but the overall paradigm need not be tied solely to one methodology. In essence, we propose that demography should seek to examine the interactions between elements of a given population, and the mechanisms driving them. These elements can be described via formal models derived from observation using inductive methods. We posit that this paradigm forms a natural extension of the previous four, and also broadens the scope of demographic research. Following Franck (2002a) and Burch (2003b), we also posit that the system-based approach can enhance the theoretical base of demography by allowing for the development of formal conceptual models.

The strength of simulation-based scenario generation approaches provides one illustration of the potential for this kind of methodological innovation. Demography, as we have seen, has a particular strength in its ability to connect directly to practical, policy-relevant issues (Xie, 2000; Morgan and Lynch, 2001). Methodological enhancements like those outlined above can push this particular strength even further. Bayesian approaches allow for formal statistical decision analysis, and thus support efforts in planning (Bijak, 2010). System-based approaches, when coupled closely with statistical analysis techniques, provides a simulated environment in which policy-makers can investigate a range of possible policy changes. This kind of experimentation is made possible by coherent scenario generation, in which the behaviour of simulated individuals closely follows empirical patterns for statistical individuals observed via demographic data (Courgeau, 2012).

The predictive horizon for demography is thought to be approximately one generation (Keyfitz, 1981), so scenario generation augmented with statistical analysis of model results allows for the exploration of more possible futures (Bijak, 2010). Utilising well-constructed simulation models to investigate these scenarios allows us to examine interactions that drive macro-level patterns of population change in more detail, while also removing some of the limitations of traditional data-heavy statistical methodologies (Silverman et al., 2011). Thus, this application of a system-based approach demonstrates the benefits of an effective combination of the empirical strengths of demography with simulation: demographers can now study complex interactions and behaviours in artificial populations which allow for coherent scenario generation. We have already seen some examples of this type of inductive, empirical system-based approach in the literature – see Klabunde (2014).

A Functional-Mechanistic Research Programme for Demography

Having established the need for, and utility of, a systembased approach in demography, how can we ensure that this new paradigm conforms to a productive classical scientific research programme? We see such an approach extant in

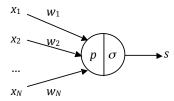

Figure 1: The McCulloch and Pitts (1943) model of a single neuron. Adapted from Franck (2002: 143).

the natural sciences since Francis Bacon. We propose that a move toward system-based modelling as a fifth paradigm presents an opportunity to reconnect with the classical scientific research programme, and in so doing, establish demography as a true model-based science rather than a 'science in the making' (Courgeau and Franck, 2007).

As an illustrative example, consider the famous neural model produced by McCulloch and Pitts (1943), pictured in Figure 1. This model was enormously influential, and led to the development of artificial neural networks some years later. When we look closely at this model, what is actually represented by this simplified neuron?

This model does not represent the physical structure or chemical behaviour of the neuron – we see no representation of the neuron's shape, its genetic material, membrane, etc. What McCulloch and Pitts did was to observe the behaviour of the neuron and represent its functional architecture, without which we would not see its main properties come about. They identified five main functions, which can be seen in Figure 1: receiving input stimuli; weighting inputs with synaptic coefficients; calculating the sum of weighted inputs (p); fixing a threshold of stimulation below which no signal is transmitted; and calculating the exit signal s.

Thus, this neuron model represents the functional structure of the processes that generate the observed behaviour of a neuron. However, the model ignores the causal factors underlying those individual functions – the model is entirely a formal, conceptual construction.

In one sense, McCulloch and Pitts have followed a process similar to reverse engineering: they have induced the design of the neuron from its end products. They of course have no interest in reproducing the neuron physically, and yet they followed much the same process as engineers seeking to reconstruct the design of a device from the final products. In doing so, they have inferred the structure of the essential functions of a neuron based on its behaviour (Franck, 2002b).

This method is essentially derived from the classical programme of scientific research, in which scientists try to in-

fer (induce) the functional structure which rules the process generating the property of interest¹. We refer to this method here as a *functional-mechanistic* one, as it attempts to model the structure of functions that rule a specific mechanism.

When examining social properties, we must similarly model the structure of social functions that drive social processes which generate those properties, and which are necessary to generate those properties. For example, work in demography has established that some combination of fertility, mortality and migration generate variations in population structure. Similarly, the law of supply and demand was inferred from the observation of markets and the social exchanges which generate them. Karl Marx's study of industrial production and its social organisation led him to infer the general structure of functions which drive this process – and in doing so develop the principle of separating labour and capital. These well-known results of social science were all derived from the application of this classical, functional-mechanistic programme of science.

Once we have established the functional structure underlying the process which generates our social property, we may use this as a means to identify and model social factors that have contributed this process. In doing so we may restrict ourselves to the investigation of factors which have contributed directly to the combination of functions we have uncovered. As an example, demographers take mortality, fertility and migration as the functions which define its scientific object – population change – and thus they undertake their investigations on the empirical study of these processes and social factors related to them.

We thus propose that the new system-based paradigm for demography should follow this functional-mechanistic approach. Model-building should follow a process of collecting all relevant empirical information about the social property of interest, which then allows us to uncover the social functions required by this property. Once this functional structure has been modelled, we can then proceed to the modelling of the factors which have contributed to the process which generated this social process, individual agents, institutions, groups, and so on (Franck, 2002a).

In the case of traditional demographic examinations of the key processes of mortality, fertility and migration, we can see clearly that the four previous paradigms are sufficient to answer a great deal of questions related to these processes. They also allow us to identify the presence of important interactions between various elements of human populations that contribute to these processes. Once we turn our investigations directly toward these interactions, rather than the results of these interactions as part of those key processes, then we are shifting our scientific object – and thus we need to follow the system-based approach. Simulation methods

can allow us to represent these interactions explicitly in a social context defined by our best available knowledge regarding the induced functional-mechanistic structure of the social system, and then investigate the potential impact of changes in these interactions.

The Process of System-Based Modelling

The system-based modelling paradigm proposed here brings with it significant advantages: the paradigm expands upon the previous four while incorporating insights from model-based science in other disciplines. Bringing this paradigm forward will require some substantial demands upon the demographic community, however; system-based modelling requires not only new conceptual developments regarding the relationships and interactions between elements of population systems, but also requires the development and use of new tools which are complex and often difficult to build and to analyse.

Thus we propose that the system-based paradigm would take shape as a four-step process, following on from Franck (*General Conclusion* 2002a):

- 1. Observation of the properties of a given population (data)
- 2. Inference of the formal structure implied by these properties
- 3. Using (2) as a guide to investigating social mechanisms that generate properties
- Model-based investigation of formal structures to seek verification with observed data

Note that statistical modelling and uncertainty qualification could serve as a means to infer the formal structures from data in steps (1) and (2).

As we have seen, multilevel modelling in demography has already provided a means to develop a greater insight into certain aspects of complex population systems by demonstrating the existence of interactions between parts of those systems. System-based modelling allows us to move forward once more by allowing us to explore these interactions as the central object of study. Simulations allow us to explore the the social factors that interest us, and generate scenarios which increase our understanding of those factors. These scenarios could represent everything from individual alterations in behaviour at the agent level, to changes in policy at a societal level (as in Silverman et al. (2013)). Using simulations in such a way also allows us to examine the non-linear impact of changes to complex, interacting social systems – a key element in the behaviour of social systems which is not possible to represent using conventional mathematical models.

In practice, system-based population modelling can rely to some extent on the existing agent-based approaches, insofar as they are subjected to the inductive principles of the

¹The type of induction we refer to here is drawn from Francis Bacon, in which induction proceeds similarly to *reverse engineering* as described above. See Franck (2002a) for further explication.

scientific method. However, a key open question remains: what principles should be followed to illuminate the inductive construction of such models? We suggest that this question is fundamental to the future direction of demography, and we have no doubt that vigorous and open debate on this question will be a vital part of efforts to take demography in a new direction.

Lessons for Social Simulation

System-based modelling will present some significant challenges for demographers in order to take advantage of these potential benefits. However, social simulation researchers are by no means exempt from this requirement to adjust their methods in response to the changing landscape in demography. For those of us who wish to use social simulation to investigate real-world populations and their properties, we may expect that the recent developments in demography will have significant impact on our research methodologies.

Looking at the field as a whole, social simulation is a continually growing area of research which continues to establish new links with numerous and varied areas of social science. The attraction of simulation approaches, particularly agent-based models, for social scientists is undeniable; the prospect of simulating individual behaviour and being able to observe the resulting macro-level effects is enticing to not only demographers, but political scientists and economists, among others.

What we have proposed here is admittedly very ambitious – our proposed fifth paradigm has implications for all of social science, in certain respects, and demands a new level of engagement between social simulation practitioners with social scientists. We argue here that the payoff for such engagement will be significant, resulting in stronger theoretical frameworks for social scientists and more empirical relevance for social simulation.

Examining the history of demography has revealed however that such a change would not obviate the need for social simulation as a separate discipline. In demography, the previous four paradigms of research remain very much present, and indeed our proposed fifth paradigm would not be suitable for certain demographic questions that are still best answered using other methods. Likewise, system-based methods may be used as vehicles for broader philosophical investigation of social systems, or as a type of opaque thought experiment (Di Paolo et al., 2000), or for many other purposes beyond prediction or the direct study of population change (Epstein, 2008). Therefore we can expect social simulation to remain and to flourish as a discipline making unique contributions to big questions about sociality in general.

However, successful application of the system-based paradigm in demography will require perhaps more methodological shifts from the social simulation side than is commonly accepted. The application of inductive, empirical methods to the simulation of human populations remains a significant challenge, and requires a different approach more firmly connected to empirical investigation and traditional scientific approaches. We hope that our elucidation of this approach and its potential benefits and pitfalls may help drive these efforts forward, and eventually lead to a productive system-based approach that gives us a greater understanding of population change.

Pseudo-Static Cooperators: Moving Isn't Always about Going Somewhere

Olaf Witkowski, Nathanael Aubert-Kato

University of Tokyo, Japan olaf@sacral.c.u-tokyo.ac.jp, naubert@is.s.u-tokyo.ac.jp

Abstract

The evolution of cooperation has long been studied in Game Theory and Evolutionary Biology. In this study, we investigate the impact of movement control in a spatial version of the Prisoner's Dilemma in a three dimensional space. A population of agents is evolved via an asynchronous genetic algorithm, to optimize their strategy. Our results show that cooperators rapidly join into static clusters, creating favorable niches for fast replications. Surprisingly, even though remaining inside those clusters, cooperators keep moving faster than defectors. We analyze the system dynamics to explain the stability of this behavior.

Introduction

The problem of the evolution of cooperation has been of interest for a long time. This problem is often tackled by using simple models, such as considering interactions to be a game of Prisoner's Dilemma (PD). Early results in game theory showed that cooperation in the case of well-mixed population was not a given (Axelrod and Hamilton 1981; Smith 1982), yet it is a very common phenomenon in nature.

The PD is a classic two-player "game" in which players are given two options: cooperate (C) or defect (D). The payoffs are such that T>R>P>S, where T stands for Temptation (D versus C), R for Reward (C versus C), P for punishment (D versus D) and S for Sucker's payoff (C versus D). It is also often admitted that 2R>T+S, meaning that cooperating is overall better for the whole system, while defecting is better for the individual. In particular, T>R and P>S means that it is always the best choice for an individual to defect, no matter the strategy of its opponent. In a system where everyone can interact with everyone else, without memory of past games or ways to distinguish opponents, defecting is obviously the best strategy. However, it has been shown that spacial locality helps cooperators survive and even thrive (Nowak and May 1993).

This early work has triggered several lines of investigation, in particular attempts to add movement. While results can be mixed in specific cases (Sicardi et al. 2009), it is widely recognized that movement is helpful (Vainstein et al. 2007). Particular interest has been given to random movement (e.g. Chen et al. 2011; Gelimson et al. 2013). In this case, though, we argue that this movement acts as a way to restrict the neighborhood of specific individuals, thus increasing locality. Diffusion (Vainstein and Arenzon 2014) is another example where the environment is sparse, allowing agents to move to empty areas. Interesting dynamics can also be obtained when the agents can actually choose on their own when and/or where to move (Aktipis 2004, 2011).

In this work, we investigate the impact of limited movement control on agents in a three dimensional space. Agents are all moving at a common constant speed, but choose their direction through the output of a neural network. We also add the possibility to communicate, through the emission of signal. Such communication might be similar to greenbeards, a phenomenon where an otherwise useless phenotype element is used to choose whether to cooperate or not (see for instance Gardner and West 2010). We argue, however, that a slightly different mechanism is at work in our case. Indeed, since the signal is also an output of the neural network, agents can adapt their response to the environment. Signal may be used both to detect where friendly agents are, or as a way to choose a strategy. In this last case, cooperation can arise both from the fact that related agents will have similar signaling (similar to kin selection), or the adaptability of an external agent (mimicry). We show that, when left to their own devices, cooperators will move more than defectors, even though their cluster is static. They also tend to communicate much more than defectors, displaying a complex dynamic to prevent defectors from taking over. We also show that speed matters, as it impacts the radius of the clus-

In the following, we describe the details of the model used in our experiments. Then, we present the proportion of cooperators over time, and compare it to the static case (no movement allowed). We also show other metrics, such as the average displacement over time and the amount of received signal over time. We then analyse those results as well as giving a simple condition on the survival of a cluster before concluding.

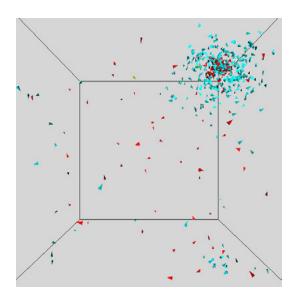

Figure 1: Graphical representation of the world in a simulation. Each agent is represented as an arrow indicating its current direction. The color of an agent indicates its current action, either cooperation (blue) or defection (red). Note the cluster of cooperators being invaded by defectors.

Model

A population of agents move around in a three-dimensional space. Each one is playing the Prisoner's Dilemma game with its direct neighbors. The strategies are evolved via a continuous genetic algorithm, that is agents with high level of fitness are allowed to replicate (with mutations) whenever possible.

Environment

Agents are placed in a three-dimensional world with periodic boundary conditions. While most previous work focuses on two-dimensional simulation, a third dimension gives the system more freedom of movement, making it easier to choose not to play (i.e. move away). The environment is a toroidal cube of size 600 (arbitrary unit), where each face connects directly to the opposite one. The world is considered to be continuous, so that agents can get arbitrarily close to each other (Figure 1), up to the precision of the simulation. Thus, the dimensionality of the simulation comes down to the choice of the agent's interaction radius.

We enforce a maximum size for the population. This makes it easier to compare, for instance, to lattices, where the number of agent also has a physical maximum due to the number of positions. Note that this maximum does not have to be equal to the number of agents at any moment in the simulation. This might also happen in lattices, for instance in Vainstein and Arenzon (2014) where partially empty lat-

tices are used to add a diffusion phenomenon.

Finally, a given simulation is prevented from stopping from lack of agents by adding one new random agent per time step if the current population is below a threshold (see Table 1).

Agents

Agents are given a certain energy, that also acts as their fitness. Each agent comes with a set of 12 different sensors. The neural network (represented on Figure 2) takes the information from those sensors as inputs, in order to decide the agent's actions at every time step. The possible actions amount to the agent's movement, a Prisoner's Dilemma action (cooperate or defect) and two output signals. The architecture is composed of a 12 input, 10 hidden, 5 output, and 10 context neurons connected to the hidden layer (see Figure 2).

The agents' motion is controlled by M_1 and M_2 , outputting two Euler rotation angles: ψ for pitch (i.e. elevation) and θ for yaw (i.e. heading), with floating point values between 0 and π . Even though the agents' speed is fixed, the rotation angles still allow the agent to control its average speed (for example, if ψ is constant and theta equals zero, the agents will continuously loop on a circular trajectory, which results in an almost-zero average speed over 100 steps).

The outputs $S_{\rm out}^{(1)}$ and $S_{\rm out}^{(2)}$ control the signals emitted on two distinct channels, which are propagated through the environment to the agents within a neighboring radius set to 50. The choice for two channels was made to allow for signals of higher complexity, and possibly more interesting dynamics than greenbeard studies (Gardner and West 2010).

The received signals are summed separately for each direction (front, back, right, left, up, down), and weighted by the squared inverse of the emitters distance. This way, agents further away have much less impact on the sensors than closer ones do. Every agent is able to receive signals on the two emission channels, from 6 different directions, totalling 12 different values sensed per time step. For example, the input $S_{\rm in}^{(6,1)}$ corresponds to the signals reaching the agent from the neighbors below.

Fitness

At every time step, agents are playing a N-player version of the prisoner's dilemma with their surrounding, meaning that they make a single decision that affects all agents around them. They get reward and/or punishment based on the number of cooperator around them. Their decision is one of the outputs of their neural network.

The payoff matrix is an extension of Chiong and Kirley (2012), where we added the distance to take into account the

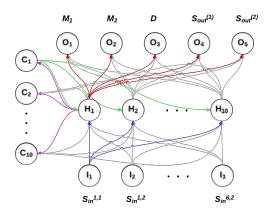

Figure 2: Architecture of the agents controller, composed of 12 input neurons, 10 hidden neurons, 10 context neurons and 5 output neurons.

spatial continuity. It is defined by:

$$\begin{cases} C: b \sum_{\text{coop} \in \text{radius}} \frac{1}{1 + distance(coop, me)} \\ -c \sum_{\text{any} \in \text{radius}} \frac{1}{1 + distance(any, me)} \end{cases}$$

$$D: b \sum_{\text{coop} \in \text{radius}} \frac{1}{1 + distance(coop, me)}$$

$$(1)$$

With b the bonus, c the cooperation cost, b>c>0, and distance the Euclidian distance between two agents. Radius represent the sphere of radius radius around the agent. Note that the agent itself is not considered part of its neighborhood. The distance is not part of the original fitness, which made sense since Chiong and Kirley (2012) are basing their simulation on a lattice, where the distance is always the same. Our version integrates nicely the fact that interactions with distant agents should be much weaker than with closer ones.

Another advantage of this fitness is that defection can also be assimilated to not playing (no cost). Note that there is also no cost and no reward for cooperating when alone.

We can see that this fitness is equivalent to the traditional PD game, since, for two agents A and B at a distance d of each other, (1) yields the payoff matrix:

$$C \quad \frac{C}{1+d} \quad -\frac{D}{1+d}$$

$$D \quad \frac{b}{1+d} \quad 0$$

It is clear that for the conditions b>c>0, this matrix correspond to a PD.

Based on the outcome of the match, agents can choose a new direction, which is similar to leaving the group in the

walk away strategy (Aktipis 2004), the main difference being that, in our case, it is also possible for groups to split. It is also similar in another aspect: there is a cost to leaving a group, as a lone agent may need time to meet others.

Evolution/Parameters

Evolution is done continuously. Agents with negative or zero energy are removed, while agents with energy above a threshold are forced to reproduce, within the limits of one infant per time step. The reproduction cost is low enough, considering the threshold, to not put the life of the agent at risk. Table 1 indicates the various parameters used for evolution.

Results

Results were obtained on a set of 10 runs, with additional sets used for control. In our setting, all agents have a constant speed, but can choose in which direction they are heading. This allows for pseudo-static behaviors by looping in circles.

While some characteristics, such as agents' movement, were strongly run dependent, the overall dynamics of the system was not. At the beginning of the run, the environment is seeded with random agents. Since all weights in their neural network are set at random, roughly half of the agents initially choose to cooperate while the other half choose to defect. This leads to a fast extinction of cooperators (Figure 3, until approximately 50000 time steps), until a group emerges strong enough to survive. The second phase follows, in which cooperators are quickly increasing in number due to the autocatalytic nature of this strategy (Figure 3).

A third step happens eventually, where defectors invade the cluster, followed either by the survival of the cluster due to cooperators running away or a reboot of the cycle. In case of survival, oscillations in the proportion of cooperators can be observed. However, this phenomenon is averaged away over multiple runs, since period and phase of the oscillations are not correlated from one experiment to the other. Figure 4 shows those oscillations in a typical run. The frequency of those phenomenon is shown in Table 2.

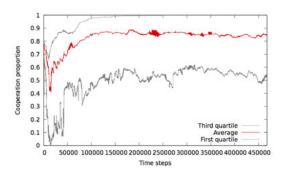

Figure 3: First quartile, average and third quartile of cooperation proportion over 20 runs. Note that agents may choose at each time step which action (cooperation or defection) they will perform, leading to high-frequency noise.

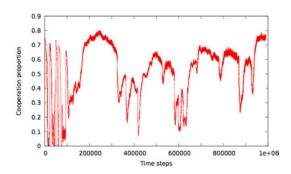

Figure 4: Proportion of cooperating agents in a typical run. Clear oscillations between the "high cooperation" state and the "low oscillation" state are observable.

Minimum	2
First quartile	2.5
Median	4
Third quartile	8
Maximum	9
Average	5

Table 2: Number of oscillations between high and low cooperations over 10^6 time steps in ten runs

As a control, we ran the simulation after removing the possibility for agents to move. In this case, cooperators have much less to fear from defectors and quickly overtake the whole population while defectors quickly exhaust their energy as well as the energy of their cooperative neighbors (Figure 5). Were a defector to appear near a cluster of cooperators, the cluster would react by "reproducing away". However, the chances to be overtaken by the defectors is much higher than in the dynamic case.

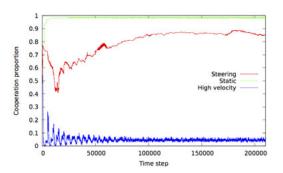

Figure 5: Average proportion of cooperators, comparison between the static and dynamic cases.

Another control was to allow agents to have a neighborhood large enough to interact with all other agents, or a speed such that the system is virtually well-mixed. In both cases, the classical result holds, with an almost homogeneous population of defectors, with the occasional cooperator obtained from random generation.

Finally, we observed the movement tendencies (figure 6) and signal transmission (figure 8) among the two groups of agents. The average displacement is the norm of the total movement over 100 steps (an example for 5 steps is illustrated at figure 7). It is interesting to note that, even though they mostly stay in clusters, cooperators move more than defectors. In the next section, we will attempt to interpret those results.

Analysis

The critical mass necessary for a cooperator to survive can be computed from its surrounding and from the costs of cooperation (Nowak and May 1993). Let us note R the maximum interaction radius, N the total number of agents inside the neighborhood (excluding the cooperator itself), and n the number of other cooperators in the radius. For the cooperator to survive over time, the costs have to exactly balance or be less than the benefits of cooperation. If we assume that agents are homogeneously distributed in the euclidian sphere around our focus, we can rewrite the sum over all surrounding agents weighted by the distance as an integral

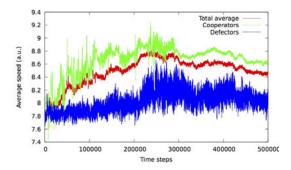

Figure 6: Average displacement of agents over a 100 steps sliding window.

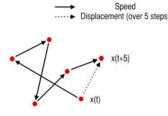

Figure 7: Illustration of the average displacement based on 5 time steps

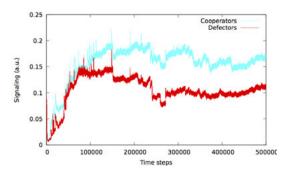

Figure 8: Average signal transmitted by cooperators and defectors.

over the densities ρ_{coop} and ρ_{all} :

$$\rho_{\rm coop} = \frac{3}{4} \cdot \frac{n}{\pi R^3}$$

$$\rho_{\rm all} = \frac{3}{4} \cdot \frac{N}{\pi R^3}$$

This gives us the equivalence:

$$\sum_{\rm coop} \frac{1}{1+dist} \simeq \int_0^R \rho_{\rm coop} \cdot \frac{1}{1+r} dr$$

Which yields:

$$\operatorname{fit_{coop}} = (bn - cN) \, \frac{3\ln(1+R)}{4\pi R^3}$$

Therefore the condition for survival is simply that the proportion of cooperators should be at least $\frac{n}{N} = \frac{c}{h}$.

Note that this condition is strongly dependent on the actual distribution of agents. The closer the cooperators, the stronger they are against external threats. Conversely, a defector at the very center of a group of cooperators can be much more damaging.

In previous work (Chen et al. 2011), it has been observed that random mobility was helping cooperator, if the speed is low enough. However, in this case, this mobility has only the effect of reducing the neighborhood. Additionally, if the speed is too high, the system gets to an almost well-mixed state, with the expected results on cooperation. Note that even the effect of high speed can be counterbalanced by a motion keeping the agents in a neighborhood.

In absence of movement, we have pseudo-movement arising from cooperators dying near defectors. As a result, the cluster of cooperators "reproduces away" from its previous position.

When movement is enabled, cooperators also appear in clusters, inside which they seem to be moving quickly. This mainly results from the major phenomenon helping cooperators, that is their autocatalytic tendencies, which might be a bias from the limit on the population size. If enough cooperators are close to each other, they will keep their energy high at all times, allowing them to reproduce as much as possible. Once the population reaches its maximum capacity, the cooperators typically represent a larger fraction of the population, especially when weighted by the energy they possess. For this reason, the cluster will remain stable until some agents die of old age, before being immediately replaced by other cooperators with a high probability.

Also, this strategy might allow them to avoid spending too much time close to defectors, while remaining constantly in the neighborhood of fellow cooperators.

The clustering is strongly dependent on signaling among the cooperating agents, hinted by the difference in signal emission between cooperators and defectors. Additionally, we performed two batch of five control runs with respectively signal on or off at all time. In the "off" case, no cluster can form, yielding a near-uniform population of defectors. The "on" case still shows qualitatively the emergence of clusters, but are much more diffuse as signaling is now ambiguous.

Conclusion

In this article, we introduced a three-dimensional model of agents playing the Prisoner's Dilemma. While it can be expected that cooperators, if any are present, would quickly evolve to form clusters, it was interesting to see that they still have a higher movement rate overall than defectors. This is even more surprising considering that those clusters do not seem to move fast. Instead, analysis shows that cooperators are moving quickly inside the cluster, which may be a way to adapt to an aggressive environment.

Additionally, comparison with the static case showed that movement made the apparition of cooperators harder, but more stable in the long run. Since it is harder for defectors to overtake a cluster of cooperators, our systems often show a soft bistability, meaning that they will eventually switch from one state to the other. It is even possible to observe a sort of symbiosis, where cooperators are generating more energy than necessary, which is in turn used by peripheral defectors. In this case, replacement rates allow cooperators to stay ahead, keeping this small ecosystem stable.

Finally, this cohesion among cooperators seems to be enhanced by signaling, even though signal might attract defectors. Additional investigation on the transfer of entropy, for instance, could be a promising next step.

Invasion of cooperation in scale-free networks: Accumulated vs. average payoffs

Genki Ichinose^{1,2} and Hiroki Sayama²

Abstract

It is well known that cooperation cannot be an evolutionary stable strategy for a non-iterative game in a well-mixed population. In contrast, structured populations favor cooperation since cooperators can benefit each other by forming local clusters. Especially, previous studies have shown that scale-free networks strongly promote cooperation. However, little is known about the invasion mechanism of cooperation in scale-free networks. Here we conducted evolutionary simulations of the evolution of cooperation in scale-free networks where, starting from all defectors, cooperators can spontaneously emerge by mutation. The purpose of this study is to reveal microscopic and macroscopic behaviors of the cooperators' invasion into the network. Since the evolutionary dynamics are influenced by the definition of fitness, we tested two commonly adopted fitness functions: accumulated payoff and average payoff. The simulation results show that cooperation is strongly enhanced in the case of the accumulated payoff when the temptation for defection is low. However, as the temptation becomes higher, cooperation persists more in the case of the average payoff. Moreover, in the case of the average payoff, lower degree nodes play a more important role in spreading cooperative strategies compared to the case of the accumulated payoff.

The emergence of cooperation is one of the challenging problems in both social and biological sciences. Cooperators benefit others by incurring some costs to themselves while defectors do not pay any costs. Therefore, cooperation cannot be an evolutionary stable strategy for a non-iterative game in a well-mixed population. In contrast, structured populations favor cooperation since cooperators can benefit each other by forming local clusters (Nowak and May (1992)). Especially, it is known that scale-free networks strongly promote cooperation (Santos and Pacheco (2005)). However, little is known about the invasion mechanism of cooperation in scale-free networks.

Here we conducted evolutionary simulations of the evolution of cooperation in scale-free networks where, starting from all defectors, cooperators can spontaneously emerge by mutation. The purpose of this study is to reveal microscopic and macroscopic behaviors of the cooperators' invasion into the network. Since the evolutionary dynamics are

influenced by the definition of fitness, we tested two commonly adopted fitness functions: accumulated payoff and average payoff. Barabási-Albert method (Barabási and Albert (1999)) is used for generating initial scale-free networks in simulations. Then, each generated network is substantially randomized by the double-edge swap method while keeping the original degree distributions. Self loops and parallel edges are avoided during the randomization.

A network is made of N nodes occupied by individuals. Each node has its strategy classified as either C (cooperator) or D (defector). Initially, all individuals are defectors. Each node i plays the Prisoner's Dilemma game (PD) with all of its k_i neighbors. The payoffs of the game are calculated as follows. Both individuals obtain R for mutual cooperation and P for mutual defection. If one selects cooperation and the other selects defection, the cooperator obtains S as the sucker of defection, and the defector obtains T as the reward for temptation to defect. The order of the four payoffs is $T > R > P \ge S$ in typical PD. We set P = 0, T = 1 + b, R=1, and S=0, where b>0 is the only control parameter, following previous studies. The payoff of individual iagainst its k_i neighbors is denoted by p_i . Here we consider two types of p_i : accumulated payoff and average payoff. The average payoff is obtained by dividing the accumulated payoff by k_i .

At the beginning of each simulation, one randomly selected individual x plays PD with the neighbors and obtains payoff p_x . Next, one randomly chosen neighbor of x, denoted by y, also plays PD with its neighbors and obtains payoff p_y . If $p_x < p_y$, individual x imitates individual y's strategy with probability $(p_y - p_x)/[(T - S)k_{\max}]$, where $k_{\max} = \max(k_x, k_y)$. Finally, another randomly selected individual z (z might be the same as x or y) flips his strategy (C will become D and D will become C) by mutation with probability m. These operations consist of one time step. We regard N time steps as one generation, in which all individuals are selected once, on average, for the strategy update and mutation. The parameter sets used in the simulations are N=5,000, \bar{k} (average degree) = 4, and m=0.005.

First, we focus on macroscopic behaviors of the cooper-

ators' invasion. Figure 1 shows the fraction of cooperators vs. time (A) and vs. temptation to defect, b (B). As previous studies already revealed, cooperation is promoted in the case of accumulated payoff than the case of average payoff (Fig. 1(A) b=0.2). This is because cooperators on hubs, i.e., highly connected nodes, can gain much greater payoffs than others. However, if the temptation to defect is high (b=0.8), cooperators cannot occupy hub nodes, and therefore the hub effect disappears and cooperation is not promoted, which was not discussed much in previous studies. In contrast, cooperation persists for higher values of b (>0.6) in the case of average payoff, although the fraction of cooperation always stays at low levels (Fig. 1(B)).

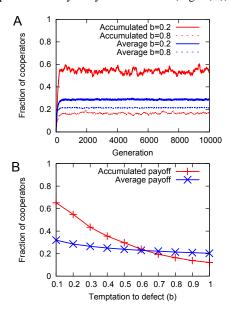

Figure 1: (A) Fraction of cooperators vs. time. Ten independent simulation runs are averaged. (B) Fraction of cooperators vs. temptation to defect (b). Five independent simulation runs (the last 1,000 generations for each) are averaged.

Next, we focus on the microscopic behaviors of cooperator invasion. Figure 2 visualizes simulation results in histograms of propagation events of cooperation, plotted over the degree of the source node of cooperation propagation and its neighbors' state ratio (1 = fully cooperative, 0 = fully defective neighborhood). In the case of the average payoff (Fig. 2(B)), lower degree nodes play a more important role in spreading cooperative strategies compared to the case of the accumulated payoff (Fig. 2(A)), because hubs cannot contribute to the spread of cooperation with the average payoff. Moreover, when cooperators spread, they need a certain fraction of cooperators in the neighbors. However, the fraction of cooperators in the neighbors tends to be low if the degree is high such as hubs. This also makes it difficult for cooperators to spread in the high degree nodes in the case of

the average payoff.

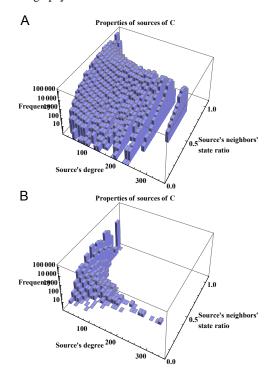

Figure 2: Frequency of propagation events of cooperation, plotted over the source node's degree and its neighbors' state ratio in the accumulated payoff (A) and the average payoff (B) (b=0.2). First 500 generations of 10 simulation runs are accumulated.

In conclusion, we investigated cooperators' invasion in scale-free networks that are initially dominated by defectors. Here we show that cooperation is promoted more in the case of the accumulated payoff only when the temptation to defect is low. This implies that the evolution of cooperation on a network depends significantly on how game players are rewarded through their game play. Moreover, from the indepth analysis of microscopic behaviors, we show that the relative importance of low degree nodes for the evolution of cooperation is much higher in the case of the average payoff, compared to the previously studied case of the accumulated payoff where hubs are known to play a major role in the propagation of cooperation.

An Agent-Based Model of Indirect Minority Influence on Social Change

Jiin Jung¹ and Aaron Bramson²

¹Claremont Graduate University ²Riken Brain Science Institute jiin.jung@cgu.edu

Abstract

The present study investigates how local majority and minority influences, in combination with an internal consistency process, affect cultural group formation and social change at a global level. We constructed an attitude updating algorithm based primarily on context/categorization-leniency contract theory. This theory postulates when, why, and how people are influenced by an ingroup majority to change an attitude (direct majority influence), by ingroup minorities to immediately change a related attitude (indirect minority influence), and eventually to change attitudes via an internal consistency process. These rules of social influence have been empirically validated in the field of social psychology. However, it is unknown how social influence processes following these rules at a local level lead to larger attitude group formation and social change (a process whereby a nascent opinion becomes the prevailing opinion) at a global level. The present study aims to fill this gap. With minimal assumptions, we implemented our social influence algorithm in an agent-based model to explore how majority and minority influences - along with internal consistency processes - each contribute to cultural group formation and social change. Our results reveal that persistently diverse attitude groups can emerge when minority and majority influences operate together; i.e., internal consistency is not a necessary condition, however it does facilitate attitudinal diversity and maintains it longer. Furthermore, even in the face of the direct majority influence, social change can occur via the indirect minority influence process when combined with internal consistency. We start here with a minimal model, but discuss directions for future expansions.

Theoretical and Empirical Foundations

Social change is the process whereby a society adopts a new belief ¹ which eventually becomes accepted as a norm. Diverse subpopulations are often seen as challengers to social stability and frequent catalysts of social change (Moscovici, 1976). Social psychologists have well-documented why, how, and when people can be influenced by such subpopulations. Furthermore, there are various theories on how the minority influence process can lead to social change (Mucchi-Faina, Pacilli & Pagliaro 2010); but little concrete research has been done to validate these postulates. A primary difficulty lies in the micro/macro differences in the phenomena: social change

happens at the level of society, whereas the minority influence process happens at the interpersonal and intra-individual levels. The present study aims to clearly establish the link between the minority influence process at a local level and social change at a global level by using an agent-based model. The agent-based model fosters examining cross-level links between agents' local behavioral rules and their generated global patterns. The model is primarily based on context/categorization—leniency contract (CCLC) theory (Crano 2010), a theory of majority and minority influences in the field of social psychology.

Minority Influence

Identifying the underlying processes fostering the prevalence of diverse subpopulations and nascent ideas has been among the dominant puzzles of the social sciences. A substantial collection of studies about conformity and majority influences (Sherif 1936; Newcomb 1943; Asch 1951, 1952, 1955; Crutchfield 1955) could not adequately address the issue until Moscovici (1976, 1980, 1985; Moscovici & Faucheux 1972) took the first step to studying the power of minority influence. Since then, research on minority influence has explicated conditions under which a nascent attitude can permeate a population to displace a prevailing attitude on the same issue. conditions include the nascent-idea-holding subpopulation's social identity (ingroup vs. outgroup), the attitudes' composition (consistent vs. inconsistent), the issue objectivity (objective vs. subjective), immediacy (immediate vs. delayed) and the focus of issue being influenced (directly to focal attitude vs. indirect influence) (Crano & Seyranian 2009). In this section, we review Moscovici's conversion theory, and illustrate how Crano's CCLC theory is developed to tighten certain aspects of conversion theory. In the following section we integrate the two theories to construct an algorithm of minority influence.

Moscovici's conversion theory. Moscovici's conversion theory contrasts the differences underpinning the motivational and cognitive processes between majority and minority influence. When individuals are confronted with an attitude counter to their own (whether the prevailing attitude or a nascent one) it creates inner conflict and tension, which results in a motivation to reduce this tension. The psychological discomfort is resolved via different processes depending on whether the counter-attitudinal source is the majority or minority attitude in their ingroup: minority

 $^{^{1}}$ In this paper we use the terms 'belief', 'attitude', 'idea', 'opinion', etc. interchangeably to refer to individuals' epistemic relationship to an issue or topic.

influence occurs through a validation process whereas majority influence occurs through a comparison process. Because the social majority may control resources or other sources of power, adopting the prevailing focal attitude is rewarding. Therefore individuals may change attitudes to comply with the group's consensus by simply comparing their own attitude to the prevailing one for some focal issue. This compliance reflects motives of group belongingness, but not an evaluation of the social majority's arguments for their positions. Consequently, the comparison results in an immediate direct influence, but the attitude change is typically superficial and may easily be changed again.

On the other hand, when someone in the society breaks the attitudinal unanimity, the person's ingroup members take notice of this salient event and the nascent idea captures the other ingroup members' attention. Even though nascent belief holders' positions are not conceived of as correct, their arguments are considered closely by the other ingroup members. At this stage of the validation process, the other ingroup members scrutinize the ideas in-depth. As a consequence, belief validation results in indirect influence (i.e., attitude changes happen in other, non-focal dimensions related to the nascent idea) and/or delayed focal attitude changes. Because ingroup members carefully evaluate the uncommon ideas, attitude changes induced by minorities via this path are stronger and last longer than those by unreflective conformity to the prevailing attitude.

According to conversion theory the most important condition for attitudes held by a minority of group members to influence other ingroup members is attitudinal *consistency*. Moscovici verified consistency's importance in his blue-green study (Moscovici 1969; 1980). Specifically, minority opinions are only influential when their attitudes are perceived as consistent and coherent (Clark 1990; Moscovici, Lage & Naffrechoux 1969; Wood, Lundgren, Ouellette, Busceme & Blackstone 1994).

Crano's context/categorization-leniency contract theory. Later research elaborated on the conditions under which attitudes held by a minority of ingroup members can have an influence on the rest of the group. This influence starts with changes to individuals' attitudes within the local ingroup, and eventually can percolate through the society and lead to global-level social changes in which the nascent idea replaces the prevailing one (Crano 2010; Martin & Hewstone 2001; 2010).

Crano's CCLC theory postulates that when ingroup members offer novel ideas that are not threatening to the ingroup they may be influential. His theory states that due to the leniency contract ² between majority and minority opinions within a group, minority influences lead to both *immediate indirect attitude changes* (i.e., changes to attitudes besides the focal countervailing attitude) and also *delayed focal attitude changes* via an internal consistency process. By contrast, majority influences lead to immediate changes to

the focal attitude, but do not affect supporting non-focal attitudes.

Thus, even though a direct change in the focal attitude is unlikely, there exists pressure to change indirect/related attitudes within the same cognitive constellation. Minority influence then becomes a function of message quality. A weak message may not lead to delayed focal change but rather temporary indirect change may occur in the direction of the gist of message. A strong message leads to an immediate indirect change, but an immediate focal change is unlikely. This minority influence toward indirect attitude changes has been empirically supported (Alvaro & Crano 1997; Crano 2000; Crano & Alvaro 1998; Crano & Chen 1998, Martin & Martin 2006).

Finally, indirect attitude changes may eventually lead to a focal attitude change via internal consistency processes. Because attitudes do not exist in isolation but rather are structurally interrelated in belief constellations, attitudes that occupy the same cognitive constellation may all be affected when one element of the set is changed. As indirect changes accumulate, delayed focal change can occur due to the motivation to maintain internal consistency within the cognitive constellation. (Crano & Chen 1998, p.1440; Fink & Kaplowitz 1993; Judd, Drake, Downing & Krosnick 1991; McGuire 1990; McGuire & McGuire 1991).

The Agent-Based Model

First we present a modeling framework that matches the social psychology theories. We developed an updating algorithm for agents that captures the majority and minority influence processes as well as internal consistency (Figure 1). In the model, we assume N agents indexed by j. Each agent can be represented by a vector of M attitudes that take one of A values; $a^j = [a^j_{\ i}] = a^j_{\ i}, a^j_{\ 2}, \ldots, a^j_{\ M}$, where each $a^j_{\ i} \in \{0,1, \ldots A\}$. We adopt the convention that agent j is the one being influenced and an agent k is the source agent who influences agent j. The source agent has attitudinal consistency if the source's attitudes take the same values (i.e., $a^k_i = a^k_{i+1} = \ldots = a^k_{\ M}$).

First each agent identifies its *local ingroup*; the collection of agents with the potential to influence it. Then each agent randomly selects one member of its local ingroup to be an influence *source*. Each agent then compares a randomly selected *focal attitude* with that of its source agent. If the corresponding attitude of the source matches that of the agent (i.e., $a^i_i = a^k_i$), social influence is not initiated because the source affirms the agent's view (Steele, 1988; Sherman & Cohen, 2006). However, if the corresponding attitudes between the agent and the source differ (i.e., $a^i_i \neq a^k_i$), this discrepancy draws the agent's attention and evokes inner conflict (Festinger 1954; 1957). This motivates the agent to react. The reaction's form is contingent upon the majority/minority status of the source's attitude in the agent's local ingroup (Crano & Seyranian 2009).

If the focal attitude of the source is the majority attitude in the agent's local ingroup, then the agent conforms to the source (i.e., changes that attitude to match the source). On the

² The leniency contract refers to an implicit agreement between majority and minority within a group in which majority listens to the minority's dissent voice to maintain the viability and cohesion of the group, and the minority also agrees that a focal change is unlikely

other hand, if the focal attitude is the minority attitude in the agent's local ingroup, then the agent examines consistency among the focal and related attitudes that the source has. At this time, the agent does not and/or cannot examine all the attitudes that the source has in its belief vector due to cognitive limitations.

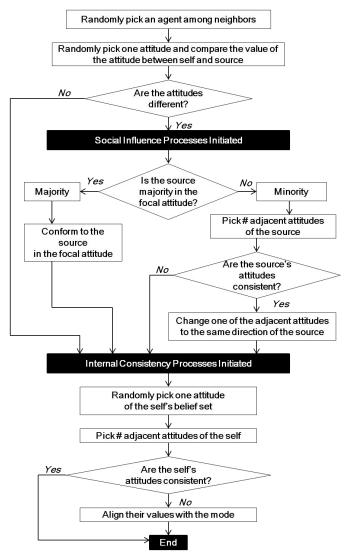

Figure 1. An Algorithm of Majority and Minority Influence and Internal Consistency Processes

As demonstrated by research on cognitive bias and bounded rationality (Simon 1957). For example, we are often *cognitive misers* (Fiske and Taylor, 1984, 1991) who prefer to process information efficiently by utilizing heuristics in our adaptive toolbox (Gigerenzer and Selten 2001, pp.37-50); people also act as *lay scientists* who systematically build knowledge from bits of evidence. Thus, in this model agents randomly select a few closely related attitudes from the source's belief vector and examine their consistency. If the closely related attitudes of the source are consistent (e.g., $a_{i,l}^k$

 $=a_{i+1}^k=a_{i+1}^k$ for focal attitude a_{i}^k)³, the agent changes one mismatched attitude out of the related attitudes (e.g., a_{i-1}^j or a_{i+1}^j) to match the source's focal attitude. However, if the attitudes are not consistent, the agent does not change any of its own attitudes. In sum, majority influence through conformity is narrow and immediate produces changes to the focal attitude while minority influence (through conversion) is less common and indirect, but has a broad impact when it happens.

Upon completion of the social influence process, the internal consistency process is initiated: these two processes are independent in the current model. In this stage, all agents turn their attention to their own belief set in order to tune their attitudes to be consistent. Each agent j randomly picks one attitude (i.e., a_h^j) in their belief set and examines if the chosen attitude and its adjacent attitudes have the same value. If the examined attitudes are not consistent, the agent tunes the chosen attitude toward the adjacent attitudes. This can be achieved, for example, by setting it to the modal value among adjacent values (if one exists) or by setting it to match a random adjacent attribute.

An Example

To demonstrate these processes we first consider a case in which each agent has five attitudes (M=5) with binary attitude values (i.e., $a^{j} \in \{0,1\}$). Agent j (marked in bold with gray shading in Figure 2) has an attitude vector of $a^{j} = \{11001\}$. Following our algorithm above, the agent considers its eight Moore neighbors (solid border) as its ingroup and makes a uniformly random selection of one to be its source for this turn. Assume the top left agent of the ingroup is chosen as k so $a^k = \{01111\}$. Next the agent randomly picks one attitude out of the five. Let's say a_3 , the 3rd attitude, is chosen. Agent *j* compares its value $(a^j{}_3=0)$ with the corresponding attitude of the source agent k $(a^k{}_3=1)$. Because $a^j{}_3\neq a^k{}_3$, agent j next evaluates the majority/minority status of the source agent k in the local ingroup in terms of the 3^{rd} attitude. Within a^{j} 's ingroup, there are six agents with $a_3=0$ and three agents with a=1: therefore the source's attribute value of 1 is in the local minority. Note that this evaluation is independent of the global prevalence of values for a_3 .

Figure 2. An example demonstrating the agent updating process.

Now agent j evaluates whether the source k is consistent in its attitudes within a cognitive constellation of a^k_3 . The adjacent attitudes a^k_2 and a^k_4 are considered, so the source's attitudes are consistent if and only if a^k_2 , a^k_3 , and a^k_4 are all

³ The attitude vector is assumed to wrap around so that a_I^k and a_M^k are adjacent.

same. In this example, the values of a_2^k , a_3^k , and a_4^k are all 1, therefore the agent j changes one of its mismatched non-focal attitudes to match the source's value. Among the two constellation attitudes a_4^j is the only mismatched one, thus agent j changes the value of a_4^j to the source's value and so becomes $a_4^j = \{11011\}$.

However, if the agent from the bottom right of the ingroup (with attitude vector $\{00110\}$) is chosen as the source instead, due to its attitudinal inconsistency (i.e., $a_2^k = 0$, $a_3^k = a_4^k = 1$), agent j will not change its attitude at all. Or if the agent to the left of agent j is chosen as the source, agent j will not change its attitude because the source affirms agent j's attitude.

Going back to the first case, upon completion of the social influence process in which agent j has updated its belief vector to $a^j = \{11011\}$, the agent j next randomly picks one attitude out of five again...let's say a_2 . Agent j examines if the chosen attitude a^j_2 and its adjacent attitudes a^j_1 and a^j_3 have the same value (internal consistency). Because the examined attitudes are not consistent (i.e., $a^j_1 = a^j_2 = 1$, $a^j_3 = 0$), the agent tunes them to be the same value of the mode (in this case 1). As a result agent j's attitude vector becomes $a^j = \{11111\}$. Each agent undergoes the same process (either synchronously or asynchronously) for each iteration of the model.

Implementation in Netlogo with Minimal Conditions

We implemented this attitude updating algorithm in a cellular automata-style agent based model using Netlogo 5.0.5. To keep the dynamics clear we utilize the minimal conditions necessary to capture the effects of majority and minority influence and internal consistency. In our basic setup 1600 agents populate a 40-by-40 toroidal square-grid topology (no empty spaces). Ingroups are defined as the eight agents in the Moore neighborhood – just as above.⁴

Each agent has two attitudes and each attitude takes binary values: one attitude is represented as color $(a^j{}_i: 0 = \text{yellow}, 1 = \text{blue})$ and the other as shape $(a^j{}_2: 0 = \text{circle}, 1 = \text{square})$. Thus, there are four different agent states: yellow circle (i.e., $a^j = \{0, 0\}$), yellow square (i.e., $a^j = \{0, 1\}$), blue circle (i.e., $a^j = \{1, 0\}$), and blue square (i.e., $a^j = \{1, 1\}$). Consistent agent states are therefore the yellow circle and blue square. When checking consistency the agents simply change the focal attitude to match the other attitude.

We define a *cultural group* as a collection of contiguous (including corner connections) agents sharing the same value for all (both) attitudes. We are interested in the number of culture groups as a measure of the social diversity of a given set of attitudes. However, not all groups should necessarily be weighted equally: the smaller a cultural group is, the less it contributes to the society's diversity. We account for this by reporting both the number of groups and the effective number

of groups. The effective number of groups is calculated using the inverse Simpson index (Page 2010).⁶

Simulations and Results

We simulated the agent based model to answer two questions of interests: (1) Under which rules can an attitudinally diverse population persist? (2) Under which rules can social change occur (i.e., a nascent idea becomes prevalent)? For each combination of rules and initial conditions (described below) we performed 100 runs of the model until (a) all the agents have the same attitude, (b) no agents can change attitudes, or (c) 10,000 time steps (to terminate non-equilibrium runs and facilitate analysis of extremely long convergence times).

At each step we calculate the percent of the population of each color and each shape – since there are only two values for each attribute, percent yellow is one minus percent blue and it suffices to present percent blue and percent square. We also determine the number of groups of each attitude, combined attitude cultural groups, and the effective number of groups.

When do diverse cultures persist?

To identify conditions under which a diverse cultural population persists we initially create a population with equal numbers of both colors and both shapes. The two attitudinal dimensions are assigned independently and the spatial distribution of attitudes is uniformly random.

Majority influence. The dynamics of local strict majority influence processes are already well-known to science. These systems converge quickly (~50-100 iterations) into amorphous global patterns of each cultural group. The attitude distribution becomes skewed in a way that is dependent on initial conditions and stochastic elements, but with no systematic bias toward any attitude. When internal consistency processes are in play, majority influence performs much the same as if there were just one attitude with two values.

Minority influence. This process acts to balance the prevalence of each attitude, so with equal initial quantities and a random initial arrangement, minority influence alone is a continuous and balanced stochastic mixing of the attributes across the agents. Although there are typically hundreds of cultural groups, none of them are persistent. In order to maintain internal consistency the attitudes have to line up in alternating rows or columns thus creating 40 groups of equal size in equilibrium. However, it often takes many thousands of iterations to reach this equilibrium and in the process there are usually many fewer groups in play.

⁴ The ingroup for the majority/minority influence algorithm can be defined by a variety of neighborhood topologies (e.g. grids of different types or irregular networks), the geographies of moving agents, dynamic social connections, abstract associations, etc.

⁵ Squares are shaded slightly darker to be more easily discernable.

⁶ The inverse Simpson index is a measure of the effective number of types in a population. It is calculated as the inverse of the sum of the squared proportional sizes of the groups: $(\sum_i g_i^2)^{-1}$.

⁷ Obviously this value depends only on the dimensions of the space – we find 40 groups because we use a 40x40 world and the attitudes alternate. Using an odd number of spaces (e.g. 39x39) forces a vertical or horizontal strip of constant, stochastically balanced fluctuation.

Majority and minority influence without consistency. These processes together form large, consistent cultural groups with mixed-attitude boundaries that converge slowly (over thousands of iterations) to a single consistent attitude culture (Figure 3). The groups are consistent despite internal consistency being off because in minority influence, imitation only occurs when the targets' attitudes are consistent.

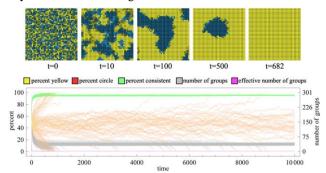

Figure 3: Results of simulation with majority and minority influence only. Screenshots from one run illustrate the spatiotemporal dynamics of consistent group formation and mixed boundaries. Plots for 100 runs showing that both outcomes are common. Most runs reach global conformity in <1000 iterations, but several take more than the 10,000 simulated. Lines appear orange because they are yellow layered on red when consistency is high.

Majority and minority influence with internal consistency. Majority and minority influences, in combination with internal consistency, create a system which has more, smaller cultural groups that come in an out of existence at a high rate. Even thought the system eventually converges, it typically takes much longer (ten times the iterations). Also, the majority and minority status of attitudes is erratic at the global scale: social change often happens, but it often switches back throughout the runs (Figure 4).

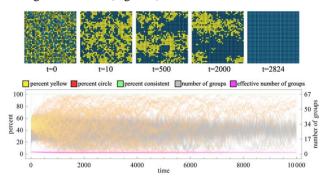

Figure 4. Results with majority and minority influence and internal consistency. Screenshots reveal the more fragmented nature of the groups and the lack of long-lasting coherent groups. Erratic time series and highly variable halting times across 100 runs reflect the stochastically balanced mechanisms.

Summary. Populations of diverse cultures will persist under either minority or majority influence alone (with or without internal consistency). When minority and majority influences work together, the system will always converge to a uniform population; however, this may take an extremely long time and even longer when internal consistency is in play. Interim

patterns of heterogeneity are more dynamic when internal consistency is in play.

Which mechanisms generate social change?

Next, we simulated the model to validate Crano's conjecture that minority influence at the local level can lead to social change at the global level via an internal consistency process. We also explore whether social change can be led solely by minority influence, and whether it is robust against the effects of majority influence. We initialize the system with a randomly chosen 1% of the agents holding the nascent attitude (yellow; i.e., $d_I = 0$) while maintaining equal initial populations of shape.

Minority influence alone. The indirect minority influence process will always spread a nascent attitude from 1% of the population toward 50% of a population. After reaching approximately half of the population, however, minority influence balances the two attitudes in a constant stochastic churning of both color and shape (as described above). Thus indirect minority influence alone cannot lead to social change. (Figure 5). Minority influence plus internal consistency also brings the population up to the roughly 50% point in every run, after which the dynamics mirror the case above.

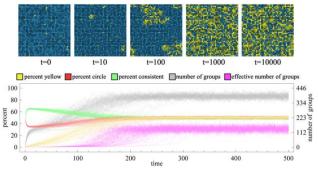

Figure 5. Screenshots show the growth in popularity of the nascent attitude up until the system becomes stochastically mixed at roughly equal proportions. Note also the alignment of the shape attitude in the early stages into locally balanced configurations. Though every run is distinct in its particular spatiotemporal arrangements, the dynamics are consistent across 100 runs. This plot is truncated to 500 iterations to highlight details of earlier periods.

Minority influence facing majority influence. In the face of majority influence, however, minority influence cannot spread the nascent attitude. Majority influence dominates minority influence process on the color attitude and so the system quickly converges to all blue. Thus social change does not occur. Minority influence (which imitates an attitude only when consistent) quickly eliminates circles from the population as well to establish a monoculture (Figure 6).

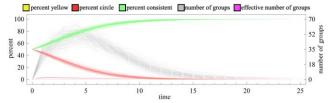

Figure 6. With only 1% of the population initially holding the nascent attitude, majority influence quickly dominates the effects of minority influence and uniformly spreads the prevailing idea.

Minority influence and internal consistency facing majority influence. Consistent with Crano's conjecture, the indirect minority influence process in combination with internal consistency *can* spread an initial minority position in the face of majority influence. Even though a system converges to the prevailing attitude in 75% of the runs (Figure8), there are chances for a nascent attitude to temporarily or even permanently be globally adopted (i.e., social change occurs) (Figure7).

Note that the initial 1% of agents that are yellow is immediately expanded in the first iteration when agents enact the self-consistency rule. Approximately half of the blue circle agents will make themselves consistent by becoming yellow circles – that's an additional 24.25% of the agents on average. We address this in future work (described below) by identifying the relationship between the number of initially consistent yellow agents and the success of social change.

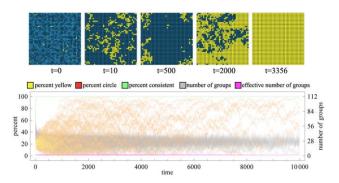

Figure 7. Screenshots from one run demonstrate the high volatility of the attitude proportions. The time series from 100 runs highlight this long-lasting volatile behavior.

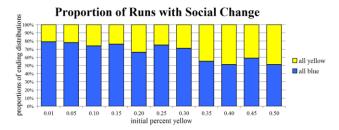

Figure 8. This chart shows the proportion of 100 runs for each ending distribution of the color attitude with all three rules activated. These runs were all taken to equilibrium regardless of the time step. Despite the high volatility of the dynamics, there is an increasing tendency to achieve social change with increasing initial percent holding the nascent idea.

Summary. In the face of the direct majority influence, social change can occur via the indirect minority influence process in combination with the internal consistency process. The indirect minority influence process alone (without the internal consistency rule) cannot spread an initial minority position

against the direct majority influence. However, this may be the result of an artifact of increasing the initial population of yellow agents through the internal consistency rule.

Discussion

The present study aims to investigate how direct majority and indirect minority influences at the local level, in combination with an internal consistency process, lead to cultural group formation and social change at a global level. The algorithm was constructed based primarily on the psychological rules posited in Crano's CCLC theory.

Majority influence immediately influences an individual to adopt the focal issue attitude due that is most common among its peers. The rules of minority influence are more complex. Ideas held by a minority of one's ingroup can also be influential, but they act indirectly on a non-focal attitude in the same attitude constellation. Furthermore, this influence only occurs when those holding the minority view are consistent in their own views. As indirect attitude changes accumulate, delayed focal change can occur through a motivation to maintain internal consistency. Indirect changes followed by consistency changes can lead an idea originally held by just a few individuals to take hold in a whole population in the right conditions. This is social change.

We tested for social change by seeding a population of 1600 agents randomly with 1% having the yellow attribute, while the shape attribute remains equally distributed. Majority influence alone, or with internal consistency, quickly removes the nascent idea form the population. Minority influence – alone or with internal consistency – reliably brings the nascent idea from 1% to 50% of the population, but naturally cannot achieve social change because the mechanism always promotes the attitude that is less popular.

When majority and minority influence are used together, but without internal consistency, majority influence dominates and the population quickly converges to the prevailing idea. When internal consistency is added, half of the initial bluecircle agents immediately become yellow-circle agents. This boost to the nascent idea holders often suffices to stop quick majority domination. Furthermore, the requirement that agents be consistent ensures that minority influence is engaged in each individual's mechanism because the minority attitude is always consistent. Although social change is possible under these conditions, it is unlikely. The likelihood depends on the initial percent of the population holding the nascent idea, and also on the micro-structure of their locations and the many stochastic elements in the model. Finally, although these simulations always end in one homogeneous equilibrium or the other, the time to reach the equilibrium can be extremely long (e.g., as much as 20,000 iterations). With mixed ideas persisting for so long, other mechanisms may interject to alter the balance.

In addition to social change, we are interested in the ability of these psychological mechanisms to maintain a diverse set of attitudes within a population. Cultural groups are communities of connected individuals who share all their (relevant) attitudes. The formation of coherent cultural groups from a random initial distribution of attributes is

important because these cultural groups can provide safe proving grounds for incubating new ideas.

Majority influence alone, or with internal consistency, succeeds in producing large cultural groups. These grouped patterns are equilibria because each agent's local neighborhood of eight agents has at least four agents of the same attitude. Without consistency checks the attributes are influenced independently, creating a multi-layered pattern in which all combinations of the attitudes persist.

In contrast to the equilibrium cultural groups formed by majority influence, the groups formed by minority influence are in constant flux. Without internal consistency, the process acts as a balancing stochastic process that ensures all attributes are roughly equally represented. There are a large number of cultural groups, but they are very small and are not persistent. They fail to capture the phenomena we wish to pick up as cultural groups; instead, they are just temporary patches of attributes. Adding consistency induces another equilibrium condition, but a mixed one. Every agent must be the minority of it local neighborhood and this is only achievable by having an even number of straight rows or columns. This is also not the sort of cultural groups identified in the literature, but rather an artifact of the model.

Combining all three mechanisms produces an interesting dynamic of cultural groups reminiscent of coherent structures in Conway's Game of Life (Conway 1970), although the stochastic elements in the current model complicates a microscopic analysis of recurrent patterns. Large and small groups of both consistent cultures can persist for long periods, "float" across the screen, rise up, and die out. As is the case with any cellular automata, these seeming movements are the result of changing attributes of stationary agents, but the population-level patterns are intriguing dynamical features of these mechanisms not anticipated by the social psychological theories.

Other features of these simulations worthy of discussion include the long time-spans of many runs, the non-equilibrium nature of some behaviors, and the volatility of populationlevel patterns. The preferred analytical technique among many social scientists involves equation-based modeling that focuses on equilibrium of outcomes or distributions. However, our results highlight the need to model and understand the dynamics of the long time-spans before equilibrium conditions are reached. Furthermore, in some cases we can foretell the outcome after a few iterations through feedback effects among clusters. In other cases (such as when all three mechanisms are active), the population can shift widely from one extreme to the other in just a dozen iterations, making reliable prediction impossible. Although we report the distribution of equilibria as a function of initial population attributes, a deeper analysis of the interim dynamics is more likely to improve our understand of the phenomena.

Limitations and Future Direction

Our goal in this paper is to present a minimal model capable of embodying the mechanisms of majority and minority influence as described in the social psychological literature. These theories, however, are purported to have much wider and deeper application. In order to fully engage the literature expansions must be made to both the simulations and the theories.

Expanded attitude space. The first obvious augmentation is to incorporate longer attitude vectors and more variations per attitude. We would like to test the sensitivity of the dynamics to the size of this attribute space a la Axelrod (1997), but the theories themselves need further refinement to handle influence in cases in which no attribute holds a majority or clear minority. What influences reign in a pluralistic environment?

More sophisticated agents. Our agents fully populate a torus space in a regular lattice – a common feature of theoretical agent-based models. More realistically agents would migrate, change interaction partners, have heterogeneous neighborhoods, and these behaviors would also be contingent on local opinions. Furthermore they could reproduce, mutate, or undergo selection processes. With this prototype model, we are able to clearly ascertain the link between agents' behavioral rules and system-level patterns.

Internal consistency force. Our findings show that the internal consistency process plays a key role in social change. The next question is how the strength of internal consistency affects social change; specifically, what is the relationship between the strength of internal consistency checks and the occurrence of social change? This question can be answered by varying the probability that a check is performed, and/or by changing the number of attitudes that are put in line (after we add more attributes).

Objective vs. subjective issues. Attitudes may address objective or subjective issues. Objective issues have a correct belief, such as the weight of a particular ox. Subjective issues (aka, mere opinions such as what color is "in" this season) reflect the converging of ideas in the population. Crano argues that for objective issues, a nascent attitude is scrutinized by counter-attitudinal individuals, which may lead to an immediate focal change if the attitude is correct. Depending on objectivity/subjectivity of issues, different rules may govern agents' influence processes. In future studies, we can construct and compare two models where different rules are implemented depending on objectivity/subjectivity of issues.

Conclusions

Majority and minority influence are important and well-studied topics in the field of social psychology. Due to the limitations of empirical methodologies, however, theories and empirical research focus mainly on explicating interpersonal and intra-individual psychological rules of social influence. They neglect how such rules lead to larger level group phenomena such as social change and cultural group formation. Most of the claims linking interpersonal/intra-individual-level rules and group/society-level patterns are merely conjectures. The present study is an attempt to provide a detailed connection between the individual and social layers through simulation.

We implement the social influence rules postulated in Crano's CCLC theory in an agent-based model with minimal assumptions. Simulation results demonstrate that in the current formulation the indirect minority influence alone cannot lead to social change in the face of the direct majority influence. However, our results also show that in combination with an internal consistency rule, the three processes together can in some scenarios lead to social change. Furthermore, both the majority and minority influence processes can lead to the formation of diverse cultural groups of distinct kinds.

The current study shows the partial validity of the conjecture that the social change at a societal level occurs through indirect minority influences process at the local level in combination with the internal consistency process. Our study reveals that all three forces are necessary for social change. The indirect influence process triggered by counterattitudinal ingroup minority alone cannot make social change occur in the face of majority domination. What is necessary is individuals' motivation to maintain internal consistency in their attitudes, to emulate consistent minority attitudes, and to adopt popular ideas both old and new.

Acknowledgements

We would like to gratefully thank Dr. Scott Page for his feedback on the model in the early stage of this project and Dr. William Crano and Dr. Patrick Grim for their insights for future directions.

The Origin of Culture: Selective conditions for Horizontal Information Transfer

Miguel Gonzalez¹, Richard Watson¹, Jason Noble¹ and Seth Bullock¹

¹Institute for Complex Systems Simulations, University of Southampton, UK SO17 1BJ mgc1g11@soton.ac.uk

Abstract

Culture is a central component in the study of numerous disciplines in social science and biology. Nevertheless, a consensus on what it is and how we can represent it in a meaningful and useful way has been hard to reach, especially due to the multifaceted aspects of its nature. In this work we dissect culture into its most basic components and propose horizontal information transfer as the most crucial aspect of it. We discuss the two fundamental processes that are required for culture to emerge in an evolutionary context, namely: high imitation error rates and survival selection. To show how each of these components affect the emergence of culture, a genetic algorithm was explored for a range of conditions. Here, we formalize when and how a population is said to move from biological to cultural evolution and why such a transition radically changes its evolutionary dynamics. Our results suggest that horizontal transfer of information in cultural systems requires the evolution of survival enhancing traits rather reproduction enhancing ones. We consider this requirement to be key for the evolution of rich cultural systems, like the one present in humans.

Introduction

Not only has the human species been able to adapt to a massive range of environments, but we have also transformed them to suit our needs. Culture is said to be one of the primary drivers for the accelerated pace at which we are able to establish and grow in new areas. (Boyd, 1985; Richerson and Boyd, 2006). Its origins are not fully understood but we know that our biological evolution must have set the stage for its emergence. In other words, just before we became a cultural species, we evolved to a point where primitive forms of social learning were possible (Richerson and Boyd, 2006). Literature offers numerous concepts of culture, for some researchers in the social sciences a superorganic view of culture, that is detached form biology, seems to offer a better and more useful explanation for the phenomena that we observe in our societies (Kroeber, 1948; Ingold, 1986). From this point of view culture would start from our biological nature but once it takes off it will be an independent process with no major feedbacks with our biological traits. For others, biology is in constant relation with culture in deeply intertwined ways (Richerson and Boyd., 2001; Rogers, 1988). We agree, as many studies suggest, that culture has been shaped by our biological history and in return our genetic traits have evolved in response to it (Richerson and Boyd, 2006; Holden and Mace, 1997). Nevertheless, in this work we focus on the disengagement process between genes and phenotype for a particular set of evolving characteristics represented as a vector of binary traits to be optimised. This might associate our model with a more superorganic view of culture, but as it will be discussed, our analysis focuses on the evolution of traits that would spark the emergence of culture rather than on the long term interactions between genes and cultural evolution.

We maintain that culture is an outcome of genes giving rise to and interacting with an evolving environment of ideas and behaviours. Cultural variants, the equivalent of alleles in genetic systems, compete for a space in our minds and are transmitted by means of social learning (imitation and teaching), they can alter our behaviour and in many ways override some of our most basic hardwired instincts. But culture, is also population level phenomena and needs to be defined as one. Considering this, we could say that culture is: the set of behavioural traits that are not the direct result of genetic expression but rather the product of an evolving pool of variants that are stored and transmitted within and between overlapping generations of individuals, by means of social learning. This important concept is discussed in the literature and sets a starting point for our dissection (Avital and Jablonka, 2005; Richerson and Boyd, 2006). A way to understand such a concept is to think of an individual developing in social isolation. This individual would not have the culturally evolved traits that form the phenotype of its socially interacting peers, but not all the traits missing in a socially isolated organism can be considered culture. Some are the result of instinctive interactions between members of a social group and these are also hard wired in genes. It is only when we take these life history and socially instinctive traits out, that we can identify culture as the missing set of traits.

As we said before definitions of culture are numerous and,

depending on which one we select, it can be identified as a unique trait of our species or a repeatedly occurring one in nature (Laland and Janik, 2006; Laland and Hoppitt, 2003; Avital and Jablonka, 2005; Heyes and Galef, 1996). Our definition includes several animal cases like species of birds that learn their song by imitation (Jenkins, 1978; Heyes, 1994), chimpanzees that learn to use tools and simple protocols for nut cracking (McGrew, 1998), cetaceans imitating hunting strategies and mating calls (Rendell and Whitehead, 2001) and others (Laland and Galef, 2009). Even though in animal cases the complexity and repertoire of culturally evolved traits is limited, it is in principle sensible to consider a general mechanism for the emergence of culture. Our intention, as well as previous models on the evolution of culture, is to show the adaptive character of it. But before we consider the adaptive value of culture we need to describe its peculiarity and some valuable existing contributions.

At the population level culture acts as a whole new evolutionary system. In this system, evolution can only take place as long as all the ingredients of an evolutionary process are present: Reproduction, Inheritance, Mutation and Selection. The equivalent to reproduction and inheritance is implicit in the act of social learning: information gets passed from one individual to another and most of it is received. Mutation is then introduced by errors in imitation; these errors can have positive or negative effects and in this sense are fundamentally different from the effect of individual learning, which tends to improve or adapt variants during lifetime. The balance between inheritance and mutation is crucial for any evolutionary process to occur; too much mutation and the system fails in an error catastrophe. On the other hand, excessive fidelity on information transfer and the system gets stuck on a single solution (Jong, 2002). Some critics of cultural evolution point out that the equivalency of genes with cultural variants (AKA memes) is not a sensible one, due to the low signal to noise ratio of cultural transmission (Burman, 2012). This is a valid observation, but we seem to intuitively understand that ideas learned from others are very similar to the original ideas that those others hold; if this was not the case communication would be impossible. A way to reconcile these positions is to consider the convergent nature of learning towards useful forms of variants (Dawkins, 1976). When we collate new information, noise can be dramatically reduced with further practice or reinforcement because we tend to converge to the useful form of that variant. An example: nut cracking techniques that might be transmitted with a lot of noise from adults to young chimpanzees in natural populations. Maybe the original attempt is different from the proper technique but this will eventually converge to a copy of the original strategy due to the useful result obtained by it (i.e., the nut!) .

Selection in cultural systems can come in a variety of forms, different biases in transmission have been identified and some of them are directly related to fitness enhancement (Enquist et al., 2007) others are frequency dependent (conformism) (Henrich and Boyd, 1998) and some are driven by social status (Richerson and Boyd, 2006). These biases have been discussed in the literature as potential explanations for the adaptive nature of culture. Most authors refer to the seminal paper of Rogers (1988), in this paper a very simple model showed how culture is not inherently adaptive just by means of its defined characteristics or the characteristics of an evolutionary process under natural selection (Rogers, 1988). Its premise is that adapting to a new environment by means of finding an individual solution implies a cost for the learner; this cost can be avoided by imitating others, so that in a non-changing environment an invasion of imitators would be the ESS of the system due to the avoided cost. But if environmental change gets taken into consideration then individual learners increase in frequency due to the advantage that they have over imitators copying environmentally uncorrelated information. In this way, the ESS would be a mixture of individual learning and imitation determined by the rate of change in environmental conditions. Rogers's model found that the point of equilibrium does not confer any adaptive advantage to a cultural population vs. a noncultural one; the evolution of culture considering the lack of intrinsic adaptive value is known as the Rogers's Paradox.

To solve this paradox several interesting and useful theoretical models have been developed, including extensions with transmission biases (Enquist et al., 2007), spatial dynamics (Boyd and Richerson, 1988) and population structure (Rendell et al., 2010). Here, we would like to take a step in a different direction. Rather than finding equilibria of strategies, biases or spatial structure that increase the adaptive value of culture we focus on the exploratory nature of cultural systems when it comes to finding new solutions in a fitness landscape. Particularly, we focus on the hybrid system present at the moment of transition, showing how culture originates and which are the minimal conditions for it. Our model does not consider environmental change because it focuses on the exploration and exploitation properties of biological vs. cultural systems when challenged to find novel solutions to temporally stable problems. Also, the model does not include individual learning; it merely shows the transition from instinctive behavioural traits to culturally acquired ones.

We recognize the inherent complexities of gene-to-instinct mapping and the potentially intricate mechanism for overwriting such behaviours with imitation. However, we consider that for the scope of our question such processes can be drastically simplified. Is for this reason, that in the description of our model a simple 1-to-1 map of genes to behaviour is proposed and the potential to overwrite such information with a copied behaviour is controlled by a binary switch.

Before we move our attention to the model description let us focus on individual learning and vertical imitation, both of them important for the evolution of culture, but not included in the scope of our analysis.

There is no doubt that individual learning and cultural evolution are constantly interacting and affecting one another (Richerson and Boyd, 2006; Avital and Jablonka, 2005; Rogers, 1988). Nevertheless our question looks at the adaptive value of culture as an evolutionary algorithm and this allows us to treat individual learning as an extension of instinctive behaviours. Here we consider both to be, albeit in different ways, a result of genes and developmental conditions and even though they may differ at a mechanistic level the notion that individual learning has a cognitive tax is not relevant for the scope of our question.

Also, it is sensible to assume that vertical transfer of variants is the ancestral form of imitation. Parents tend to be the most present and readily available source of information to imitate (Avital and Jablonka, 2005). Nevertheless, systems that depend entirely on vertical imitation would not be fundamentally different from genetic systems and would merely represent the same algorithm with an added substrate for information transmission. In order for culture to represent a novel evolutionary system where ideas and not organisms are selected, horizontal transmission should be included. For this reason we concentrate mostly on this sort of transmission in our analysis, only exploring its vertical counterpart in a later section. From here on we will equate the evolution of culture with the evolution of horizontal transmission, unless otherwise specified.

The Simulation Model

The model is a steady-state genetic algorithm in which each individual is represented by two strings of bits. The first string is considered the phenotype and the second the genotype. A 1-to-1 mapping from genotype to phenotype represents genetic expression. Fitness evaluations are made considering only the phenotypic information. Genotypes have an extra bit that acts has an imitation switch: if its value is 1 the individual will substitute the genetic expression string of bits in its phenotype for the phenotype of a randomly selected individual in the population. If the value is 0 the genotype string is copied into the phenotype, excluding the imitation bit. The action of imitation takes place at birth for each individual and once it has happened the phenotype remains unchanged for its lifetime.

Phenotypic imitation has an associated mutation rate, here described as μ_p . In the same way, genetic reproduction incorporates a mutation rate μ_g which also affects the extra imitation bit (switch) in the genotype string. Genetic expression, that is genotype to phenotype copying when the switch value is 0, does not include any errors. For all the results shown in this paper the value of μ_p and μ_g are fixed with a bitflip chance of 0.01 and 0.001 respectively, unless specified.

The population is initially set with an imitation switch

value of 0. and the second half of both strings of bits is set to 0s and, the first half is set to 1s. This is done to avoid mutation biases that would create an upward trend in fitness under lack of selective pressure. The fitness landscape explored in this paper is the one defined by the sum of ones in the string of bits. In this way a string of all-1 represents the optimal solution. For all the results shown here the length of the bit string is two hundred bits (L = 200), and the size of the population is one hundred individuals (N = 100). The general results can be reproduced with larger populations and larger strings of bits; smaller populations can produce different results between individual simulations but on average they would follow the behaviours here described. The processes we discuss here are relevant when the bit string is long enough for a search and optimization period of several iterations to take place. Single-digit bit strings, for example, might not reproduce the results we describe here.

Selection is established by the joint action of a reproduction function and a death function. Reproduction selects an individual of the population with a probability P_r from a Boltzmann-weighted function distribution of Fitness (Eq. 1). The death function uses the same method but with the complement of the number of ones in the phenotype vector rather than the fitness value $L-L_1$ calculating in this way the chance of dying as P_d (anti-fitness) (Eq. 2). On each iteration a mutated copy of the individual selected by the reproduction function will substitute the individual one selected by the death function.

$$P_r = e^{\frac{L_1}{x_r}} \tag{1}$$

$$P_d = e^{\frac{L - L_1}{x_d}} \tag{2}$$

Different combinations of strength between survival and fertility were considered by changing the value of the exponents x_d and x_r . Random selection for reproduction and random selection for death are also included in our results. Figure 1 illustrates the algorithm we have described here.

This model does not include crossover functions; we recognize that recombination advantages can be added to the cultural process by increasing the source of possible models to follow. Future work would be oriented towards exploring the advantage of cultural multi-parent crossover vs. bi-parental crossover in genetic reproduction. Here, we decided to focus on the effects of horizontal transfer of information.

Results

Simulations were run for a range of values (mutation rates, population size, vector length and selection strength). Results suggest that the relation between mutation rates and the type and strength of selection are critical for the evolution of horizontal information transfer to take place. Before

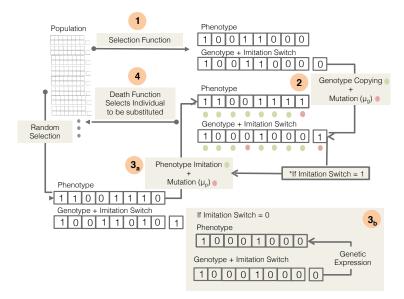

Figure 1: The diagram shows an iteration of the algorithm: (1) the selection function picks an individual from the population, (2) its genotype string is copied including the imitation switch (mutations may occur), (3a) if the imitation switch is equal to one, a random individual from the population will be selected and its phenotype will be copied with an associated imitation error. (3b) if the switch is equal to zero the bit string in the genotype will be copied into the phenotype with total fidelity. (4) The resulting combination of phenotype and genotype will replace an individual selected by the death function.

discussing these critical points it is important to describe the three possible behaviours emerging from these simulations. Figure 2 describes these scenarios.

In case A disengagement between phenotype and genotype fitness takes place early in the simulation along with a rapid growth in the proportion of imitators. Here, survival selection establishes a fitness-proportional life length for cultural variants. This case distinctively shows how the evolutionary process is taken over by horizontal imitation. Selection only evaluates phenotypes while genes get masked as soon as imitation frequency rises. Further evolution increases the gap between phenotype and genotype, making it even more costly to stop imitating and start expressing information from the genome. Eventually an evolutionary process entirely dependent on social learning finds the optimal solution and information is then maintained in individuals' actions rather than genes.

Case B is similar to A but here the selection strength for the phenotype is not enough to reach the optimal solution, this case occurs when survival selection is low $(x_d >> 1)$. Imitation, with its high mutation rate, will initially outper-

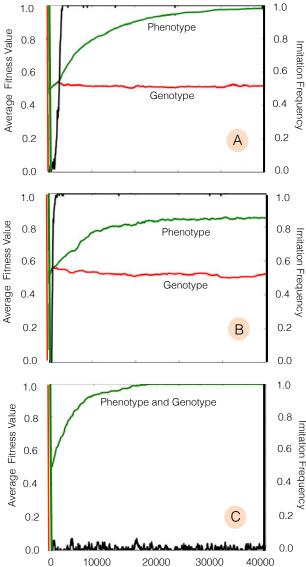

Figure 2: Single runs showing the three different scenarios: (A) Culture emerges early in the simulation under strong survival selection and the fitness disengagement between phenotype (green line) and genotype (red line) is accompanied by the sudden increase of imitation frequency (black line) ($x_d = 1$, $x_r = \infty$). (B) The fixation of imitators is also accompanied by fitness disengagement, but in this case the balance between selection and mutation prevents the phenotype form reaching the optima while the high frequency of imitation masks the genotype from selection. This case takes place under weak survival selection ($x_d = 5$, $x_r = 1$). (C) Disengagement is not present when survival selection is absent, both imitation rates stay low. Genetic evolution dominates ($x_d = \infty$, $x_r = 1$).

form the search ability of genes but eventually fail to reach the optima after disengagement. Selection on the genotype is masked making it impossible for genes to catch up. Variations of case B are rarely found under lack of survival selection; in these cases there is a chance that genetic fitness will eventually match phenotype fitness, if this trend goes beyond mid way the solution gradient (average of a drifting pattern), imitation frequency will drop to zero and the population will evolve genetically from then on.

Case C shows a standard genetic evolution scenario where both phenotype and genotype correlate all the way to the optimal solution; in this case imitation rate remains low. These genetic systems relay on vertical inheritance, which, under reproductive selection alone, is the only way to consistently optimize solutions. Simulations tend to converge to case C under lack of survival selection.

Types of Selection in Cultural Systems

In order to find the minimal conditions for horizontal transfer to evolve, we explored a range of combinations of the Boltzmann exponents in equations 1 and 2. These exponents control the strength of fitness based selection for survival P_d and reproduction P_r . The larger the value of x_d and x_r the weaker the strength of selection. Figure 3 shows a distribution of the three different cases discussed in the previous section for different combinations of Boltzmann exponents.

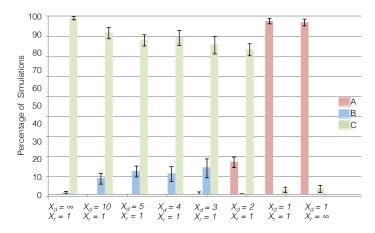

Figure 3: The percentage distribution of cases A, B and C is shown for different combinations of selection strength. Ten replicates of 100 individual simulations were run for each combination; positive and negative error bars represent a single standard deviation.

Cultural cases A and B are more frequent when the strength of survival selection increases but when selection only affects reproductive success case C is dominant. The reason for this has to do with the way horizontal imitation breaks the very notion of inheritance. Without inheritance,

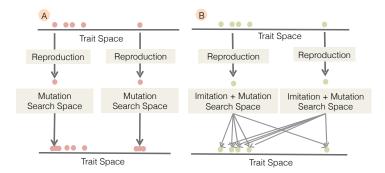

Figure 4: Comparative analysis of cultural vs. genetic search. (A) The genetic case explores an area restricted to the vicinity of the parental position in trait space. (B) Cultural evolution with horizontal information transfer establishes a common search area defined by the current distribution of phenotypes in the population, effectively getting rid of vertical inheritance and eliminating the impact of reproductive selection.

the number of offspring that an individual has is irrelevant.

In genetic reproduction each individual explores the trait space in independent lines from one another. In other words, the space of possibilities for a newborn is limited to the area where its parents currently are plus a surrounding space established by the genetic mutation rate. With horizontal imitation every single newborn in the population has the same search area, that is the current distribution of phenotypes in search space plus the imitation error area around them. A graphical representation of this is shown in Figure 4.

For cultural systems with horizontal transfer it does not matter who produces the new individuals because the algorithm stops looking at them as units of selection and instead it focuses on cultural variants. The bottom line is how long can you survive and serve as a model for others, rather than how many others can you produce. Our model links the selection of variants to the survival of individuals just like in a natural selection scenario, but it is important to reiterate, that this is not the same as selecting for the current state of independent search paths as it happens in biological evolution (figure 4A). This subtlety is a fundamental difference that changes the focus of selection from organism to variants.

These findings lead us to think that in order for horizontal transfer to evolve, with no transmission biases, a strong component of survival fitness should be present for a set of traits in the population. By extension, these types of traits would be fundamental for the emergence of culture.

In natural populations this claim is hard to test because behavioural traits have different mixtures of reproductive and survival fitness components; most species respond to some form of transmission bias (Avital and Jablonka, 2005) and evolutionary races to find new solutions for problems are hard to spot and trace. Nevertheless, we consider the findings of our model interesting from an A-Life perspective, especially due to its characteristic phenotype genotype disengagement behaviour and potential for extensions.

The Culture Advantage of Mutation Rates

Horizontal transfer without any transmission biases can generate faster adaptation compared to genetic evolution. This is mainly because the error rate of imitation is higher than mutation rates in genes. In figure 5 the average path for one hundred replicates compares the performance of a horizontal transfer cultural system (Cultural HT) with a vertical one (Cultural VT). In Cultural VT parents are the only models to imitate; this system is slightly different from a purely genetic case because the evolution of imitation frequency is still considered and both genes and variants are evolving. For comparison, a genetic case with mutation rate equal to the imitation error in cultural systems (Genetic HM) and a genetic system with a low mutation rate (Genetic LM), are included.

The trajectory described by Genetic LM is similar to that of a horizontal transfer system where the imitation error is set to the same low value as the mutation rate of genes. In similar fashion, if both mutation and imitation errors are set to a high value, the trajectory described by Genetic HM will take place. This shows how the advantage of cultural systems in Cultural VT and Cultural HT relies heavily on high error rates in imitation when compared to its low mutating genetic counterpart.

In nature, genetic mutation rates have a baseline and its random occurrence is considered a physicochemical constraint of DNA replication. Nevertheless, there are corrective mechanisms that can attenuate the effect of mutation during genetic replication (Lodish et al., 2004). The evolution of these mechanisms is considered an adaptation to the high level of contingency existing in development. Higher mutation rates could easily evolve in an organism but such a trait is undesirable due to the associated frequency of deleterious mutations arising from it. In this way, it is sensible to say that genes cannot afford to mutate as much as cultural variants due to the collateral effects on existing adapted traits.

If culture, with its higher mutation rate, is to take over genetic evolution it has to find a way to shield finely tuned behaviours that are critical for life. For this reason we would like to make the point that the term cultural evolution as described in this work should be reserved for newly established problems which could be the result of a sudden environmental change or the introduction of a new social group in the community. Our model does not describe this mechanism in detail and it merely assumes that this is the sort of problem that the hybrid system needs to tackle.

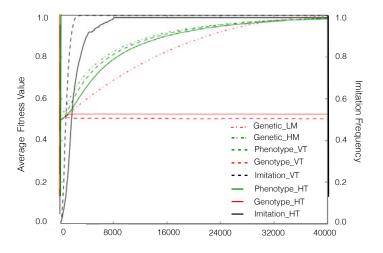

Figure 5: The average trajectory for a hundred individual simulations is shown for an horizontal transfer algorithm HT (continuous lines) and a vertical transfer algorithm VT (segmented line). Dot and segment lines represent paths for genetic evolution algorithms with mutation rates of 0.001 (Genetic LM) and 0.01 (Genetic HM). Here is shown that the fundamental advantage of cultural algorithms relies on the high error rate ($x_d = 1, x_r = \infty$).

Extensions

The model here presented is intended as a building block for future research endeavours. We think it is minimal in its assumptions and yet it produces the fundamental behaviours associated with culture. Current analysis on the embedded evolution of horizontal (vs. vertical) imitation is being developed. In addition, we are looking at the previously mentioned crossover advantage when having numerous models to copy from.

Transmission biases could easily be added by making the selection of a model to copy a function of its fitness, frequency or individual social status. Population structure is just a networked implementation away. On a networked model models to imitate would come from neighbour nodes rather than from the whole population; such a constraint could stimulate the evolution of culture by creating clusters of solutions that rarely exchange information, exploiting in this way the advantage of weak links in social networks (Csermely, 2000; Granovetter, 1983).

A more sophisticated approach would include the idea of frequency dependence and social games. Correlation between strategies in social games has been shown to increase the total benefit for individuals. An extension to the model here explained could show how culture can promote such correlations taking advantage of social learning and imitation in a game theoretic context.

Conclusions

Our model shows basic attributes of the evolution of culture. That we see the characteristic fitness disengagement between the phenotype and the genotype co-occurring with the fixation of imitation provides a clear fingerprint for culture. Within the constraints of our model, two conditions are necessary for horizontal transmission to evolve i) a high imitation error rate that provides an exploratory advantage and ii) a strong survival selection function that maintains selective pressure when imitation takes over. The mechanism here presented showed how genotypes can be masked from selection when imitators increase in frequency, and as a result a clear disengagement between phenotype and genotype occurs. We consider this key for the emergence of culture as defined in this work. Potential future extensions that could offer a clearer picture of the interaction between vertical and horizontal transmission, along with the possible effects of transmission biases, population structures, and social games are being developed.

We hope our findings lead the way to a general simulation framework to explore culture emergence and cultural evolution; the model is simple and stripped of most complexities obscuring the basic attributes of hybrid gene-culture systems, which makes it an excellent candidate for future development.

Gene-culture coevolution of language: measurement-interval dependence of evolutionary rate

Tsubasa Azumagakito^{1,2}, Reiji Suzuki¹ and Takaya Arita¹

¹Graduate School of Information Science, Nagoya University ²azumagakito@alife.cs.is.nagoya-u.ac.jp

Understanding the origin and evolution of language is key to understanding humans. The relationship between the biological evolution of language ability and the cultural evolution of language itself is extremely complex and shrouded in controversy because these mechanisms interact with each other despite the difference in their time scales (Mesoudi et al., 2011). The concept of coevolution between language and brain, in which language adapts to the brain and the brain adapts to language, is considered important in integrating biological and cultural evolution of humans (Deacon, 1997).

On the other hand, cultural linguistic change is often assumed to be much faster than biological change. For example, Chater et al. (2009) showed, using a computational model, that genetic natural selection may not keep pace with rapid language change. However, it is known that the rate of evolution has a dependence on the interval of time over which the rates are measured (Gingerich, 1993). Rates of evolution can be measured in darwins (d), which is a standardized unit of change in factors of e, the base of the natural logarithm, per millions of years (Gingerich, 1993).

$$d = (\ln(x_2) - \ln(x_1))/\Delta t \tag{1}$$

where x_1 is the mean trait value calculated at time t_1 , x_2 is the mean value at time t_2 , and Δt is the time interval between x_1 and x_2 . Fig. 1 shows an example of the measurement interval dependence of the evolutionary rate of a quantitative trait. If the evolutionary process is directional (a-i), the rates are stable irrespective of measurement time interval (a-ii). However, if the evolution process is less directional or fluctuating (b-i), the rates are inversely correlated with the measurement time interval (b-ii). This is because the fluctuation strongly affects the measured rate when the interval is short, while the general trend affects the rate when the interval is long. Perreault (2012) found that, by analyzing archaeological data, the rates of cultural evolution are inversely correlated with the measurement interval. He claimed that this explains why cultural change appears to be faster than biological change (because we tend to measure cultural evolution on a short time scale) but concluded that cultural evo-

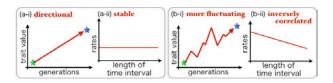

Figure 1: Examples of evolutionary trends for two quantitative traits and their associated evolutionary rates as a function of the measurement time interval.

lution is faster than biological evolution even when such a correlation is taken into account. This indicates the significance of this fine-grained comparison of evolutionary rates in the context of interactions between biological evolution of language ability and cultural evolution of language.

The purpose of this study is to clarify the relationship between the rates of biological evolution of language ability and cultural evolution of language, focusing on their measurement-interval dependence. In order to analyze this, we employ a bottom-up computational framework for investigating possible scenarios for gene-culture coevolution of language, which has been proposed in our previous works (Azumagakito et al., 2013, 2014).

In this model, there are finite number of agents and languages in a one-dimensional space, and agents can communicate with each other using their shared languages (Fig. 2). Each language is represented as a point in the space, and its distance from the origin (El) represents its expressiveness, which contributes to the expected fitness benefit of a successful communication using that language. Each agent is also represented as a point and an area surrounding the point. This point represents the agent's innate language ability determined by its gene Ea, and the area represents agent's linguistic plasticity determined by its gene P. The agent can use any languages within its plasticity area for communication, incurring a cost proportional to the size of the area. In each generation, all possible pairs of agents make an attempt to communicate. If two agents share one or more languages, they can communicate successfully. This definition means that agents who can communicate with many other agents

Figure 2: The linguistic space.

using expressive languages acquired with limited linguistic plasticity will have high fitness. After the communicative interactions of agents, biological evolution of language ability occurs according to a genetic algorithm.

Subsequently, the language population evolves according to four cultural processes: 1) Cultural change: the user of a language exerts a force that drags languages towards its location, 2) Division: a language is divided into two if the drag forces strongly pull it in opposing directions, 3) Extinction: any languages that are not used by any agents in one generation do not appear in the next generation, and 4) Fusion: when the distance between two languages is small enough, these languages are united into one language. Through the above processes, the agent population and the language population coevolve.

We conducted evolutionary experiments for 20,000 generations. The results showed that the agents and languages evolved to have high expressiveness through a cyclic coevolutionary process, which was discussed in our previous study (Azumagakito et al., 2014). Here, we measured evolutionary rates for languages (in terms of average El) and agents (in terms of average Ea).

Fig. 3 shows a typical coevolution process between (a) the average agent's trait and (b) language expressiveness, and their evolutionary rates measured over several time intervals. The x-axis ranges from 5000 to 20000 generations of evolution is not shown because there is no remarkable change of tendency. We see that both rates of evolution change dynamically and there are peaks for $\Delta t = 200$. These peaks correspond to rapid evolution of agents and languages. We also see that the rates of language evolution tended to be higher and fluctuate more than those of biological evolution in the case of $\Delta t = 200$. However, rates of language evolution became slower than biological rates when the time interval was long ($\Delta t \geq 1000$). In addition, Fig. 3 (c) shows linear approximations for both rates as a function of the time interval. The negative slopes clearly show their measurementinterval dependence. There was a statistically significant difference in the slopes (p < 0.05). Note that cultural rates were faster than biological rates when they were measured over a short time scale, but this reversed when the time interval was longer. This means that the measurement-interval dependence of the evolutionary rate of language is stronger than that of the rate of biological evolution. We propose that this is due to the lack of directionality in cultural evolution. This implies that biological evolution is more directional than cultural language evolution, and could therefore keep pace with language evolution.

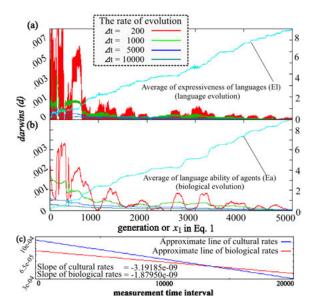

Figure 3: A typical coevolution process between (a) the average agent's trait and (b) language expressiveness, and their evolutionary rates measured over several time intervals. (c) Linear fits for both rates against the time interval over which the rates are measured.

Extended Abstract

In this work we demonstrate the theoretical possibility and explore the implications of developing artificial life that functions as an autonomous business within the real-world human economy. By drawing on the Viable Systems Approach (VSA), we introduce the new concept of an "organismenterprise" that exists simultaneously as both a life-form and a business. We then reconceptualize the anthropocentric understanding of a "business" in a way that allows an artificial life-form to constitute a "synthetic" organism-enterprise (SOE) just as a human being functioning as a sole proprietor constitutes a "natural" organism-enterprise. Practical obstacles to the creation of SOEs are considered, along with possible means of surmounting them. SOEs would move a step beyond current examples of artificial life that produce goods or services within a simulated world or play a limited role within a human business: rather than competing against artificial organisms in a virtual world, SOEs could evolve through competition against human businesses in the real-world economy. We consider concrete examples of SOEs and conclude by highlighting legal, economic, and ethical issues that arise when a single economic ecosystem is shared by competing human and artificial life.

The concept of an "organism-enterprise." A business is defined as "the organized effort ... to produce and sell, for a profit, the goods and services that satisfy society's needs" (Pride, et al. 2014). Management theorists have drawn on biology to better understand the structure and function of such business organizations. Our research utilizes a systems theory grounded in neurophysiology, the Viable Systems Approach (VSA), that allows us to understand a business as an autopoietic organism or "system" that dwells within the ecosystem of a larger economy or "suprasystem" (Beer, 1981; Barile, et al. 2012). Within this ecosystem, a business must compete against other organisms for limited resources and adapt to environmental demands. In our human economy, individual businesses are born, grow, and die, and taken as a whole, this array of businesses forms an evolvable system.

We begin by considering one unique instance in which a business is not simply "analogous to" a living organism, but identical to it: namely, the case of a human being who functions as a sole proprietor. In this situation, a single system simultaneously satisfies all the requirements of being both a life-form and a business. Building on this case, we introduce the idea of a unitary "organism-enterprise," a concept that is already instantiated in the form of at least 20 million "human organism-enterprises" within the United States alone.

Reconceptualizing business to include synthetic organismenterprises. Utilizing VSA and the concept of an organismenterprise, we analyze the traditional anthropocentric understanding of business as an exclusively human activity to consider whether an artificial life-form could serve as a "synthetic organism-enterprise" (SOE) that is both a life-form and a business. We show that this is indeed possible, but requires us to transform our understanding of business.

For example, human businesses are traditionally described as requiring four kinds of resources: 1) human; 2) material; 3) financial; and 4) information. To replace this anthropocentric understanding, we propose that a business be understood more generally as requiring: 1) agent resources; 2) material resources; 3) value-storing media; and 4) information. Similarly, a human business requires functional units filling roles in production, finance, marketing, human capital management, and information technology. Drawing on VSA and the case of a human sole proprietor, we consider the ways in which these functions can be understood more generically, in such a way that they can also be performed by current and proposed forms of artificial life. We give particular attention to the role of "profit" in a human business and formulate an account of its correlate for an SOE: it is the difference between resources expended and received in exchanges in the suprasystem that provides an SOE with a potential for growth and insurance against environmental uncertainties.

Figure 1 provides an overview of our reconceptualized "business process cycle," which can be carried out equally well by either a human business or an artificial life-form that has been designed or evolved to fill a business role within a larger economic ecosystem.

Current obstacles to an artificial life-form as organismenterprise. Artificial life-forms have already been designed that are capable of carrying out this entire business process cycle within the simulated ecosystem of a virtual world (Kubera, et al. 2011). Similarly, there are artificial life-forms capable of carrying out parts of this cycle within human businesses in the economy of the "real world" (Kim and Cho, 2006). However, our survey of the field has not yet identified any existing artificial life-forms capable of carrying out this entire business process cycle within the real-world human economy. We identify a number of obstacles that currently prevent this from taking place, and we highlight those areas within the business process cycle that pose the greatest challenge for the future development of SOEs.

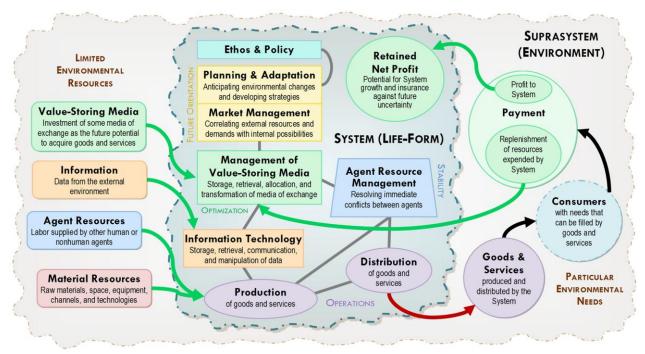

Figure 1. A reconceptualized business process cycle that applies to a human organism-enterprise as well as to a synthetic organism-enterprise (SOE) that has been designed or evolved to provide goods or services within some ecosystem.

Designing artificial life-forms that can complete the business process cycle. We briefly consider some approaches to overcoming these obstacles, so that an artificial life-form can not only meet the minimal requirements for constituting a synthetic organism-enterprise but potentially even excel in the role of entrepreneur (Ihrig, 2012). We especially consider the potential of virtual goods and cryptocurrencies to overcome the difficulty of providing an SOE with an effective means of utilizing value-storing media (Scarle, et al. 2012).

Evolution of artificial life through competition in the human economy. An SOE producing goods or services of value to human beings would be capable of competing against human businesses in the real-world economy. We consider whether these competitive pressures would be sufficient to drive evolution among SOEs. By utilizing the concept of "clockspeed" as a measure of the speed at which businesses must adapt and compete, we identify industries in which SOEs would likely evolve at an accelerated rate (Fine, 1998).

Specific examples and practical implications of artificial life as entrepreneur. An autonomous artificial life-form that is capable of securing all of the resources needed for survival and growth directly from the real-world human economy would in principle no longer be dependent on its human designer. Such possibilities are not risk-free: we imagine the case of computer viruses that are capable of evolving self-adaptive behavior rather than mere polymorphism or metamorphism (Beckmann, et al. 2009) and that no longer steal for the financial gain of human cybercriminals but to provide resources for their own survival, growth, and autonomously chosen pursuits. We also consider more optimistic cases, such as the development of artificial life-forms that build successful "careers" as artists or composers

or IT service-providers within the human economy and that are able to evolve in response to economic demands, without the active guidance or support of a human designer. Finally, we propose areas for future research to address the moral, legal, and economic issues that will arise from the existence of synthetic organism-enterprises and the fact that the productive and competitive capacities of successful SOEs could far surpass those of traditional human businesses.

Boolean Networks, Neural Networks and Machine Learning

On the Relationship between Local Rewiring Rules and Stationary Out-degree Distributions in Adaptive Random Boolean Network Models

Taichi Haruna¹ and Sayaka Tanaka¹

Abstract

We discuss the relationship between local rewiring rules and stationary out-degree distributions in adaptive random Boolean network models that evolve toward criticality. We derive a theoretical formula for the relationship via a master equation approach. The theoretical result is shown to agree well with numerical simulation in three representative cases.

Introduction

Coupling between structural change of a network and dynamics on it is important to understand functioning of complex systems. Many models have been proposed to capture various types of couplings so far. They are called adaptive networks (Gross and Blasius, 2008; Gross and Sayama, 2009). One interesting type of the adaptive network model is the one in which network topology evolves toward dynamical criticality by a local rewiring rule. Several adaptive network models of this type have been studied numerically so far, for example, extremal dynamics on random networks (Christensen et al., 1998), random threshold networks (Bornholdt and Rohlf, 2000), neural networks (Bornholdt and Röhl, 2003; Meisel and Gross, 2009) and random Boolean networks (Liu and Bassler, 2006).

Random Boolean network (RBN) is a model of gene regulation networks (Kauffman, 1969, 1993). It has been shown that RBN exhibits a continuous phase transition from ordered to chaotic dynamics by a mean-field approximation (Derrida and Pomeau, 1986; Luque and Solé, 1997). In recent years, several approaches to map real-world networks to RBN have been proposed and shown that real-world networks are working close to criticality (Rämö et al., 2006; Balleza et al., 2008; Nykter et al., 2008). Biological significance of criticality has been also discussed: balance between robustness and evolvability (Aldana et al., 2007) and maximum information coordination (Ribeiro et al., 2008).

An RBN consists of a set of nodes connected via regulatory relationships represented as Boolean functions. Let the number of nodes be N and the in-degree of node i k_i . Each node can take two values 0 and 1 corresponding to off and on of a gene, respectively. For each node i, a random

Boolean function $f_i: \{0,1\}^{k_i} \to \{0,1\}$ is chosen. For each input $\mathbf{x} \in \{0,1\}^{k_i}$, the output of $f_i(\mathbf{x})$ is determined to be 1 with probability p and 0 with probability 1-p, where 0.5 is a parameter. Here, we consider the standardcase p = 0.5. The value of each node is updated by a given random Boolean function. For the time evolution of the whole system, we consider the classical synchronous updating scheme. Namely, we assume the existence of a global clock t and all nodes are updated synchronously. Let $x_i(t)$ be the value of node i at time step t. The state of the whole system is defined as $\mathbf{x}(t) = (x_1(t), \cdots, x_N(t))$. In the limit of large N, the dynamics of RBN is ordered if $z < \frac{1}{2p(1-p)}$, critical if $z=\frac{1}{2p(1-p)}$ and chaotic otherwise (Derrida and Pomeau, 1986; Luque and Solé, 1997), where z is the average in-degree of the underlying network of the RBN. When p = 0.5, the critical average in-degree is $z_c = 2$.

In this paper, we focus on adaptive random Boolean network models and discuss the relationship between local rewiring rules and the stationary out-degree distributions (Liu and Bassler, 2006). Real-world gene regulation networks have heavy-tailed out-degree distributions (Aldana et al., 2007). It is interesting problem whether we can reproduce this feature by an adaptive random Boolean network model that evolves toward criticality. (Liu and Bassler, 2006) reported that the stationary out-degree distribution is wider than the stationary Poisson-like in-degree distribution in their numerical simulation. However, its actual form is unknown. (MacArthur et al., 2010) studied a different type of adaptive network model that evolves toward criticality with a stationary heavy-tailed degree distribution. However, its mechanism is unclear. Here, we extend the model proposed by (Liu and Bassler, 2006) and obtain an theoretical expression for the relationship via a master equation approach. We also consider a new adaptive network model whose local rewiring rule is governed by local information transfer to examine whether our theoretical treatment is sensitive to the detail of local rewiring rules or not. We show that in both adaptive network models our theoretical result agrees well with numerical simulation for three representative cases: Poisson, exponential and truncated power law stationary out-degree distributions.

This paper is organized as follows. In section 2, we review two adaptive random Boolean network models considered in this paper. In section 3, we present the formula relating local rewiring rules and stationary out-degree distributions and compare it with numerical simulation. We derive it in Appendix. In section 4, we discuss meaning of the result and connection with real-world gene regulation network topology.

Adaptive network models

In this section, we introduce two adaptive random Boolean network models. The first one is an extension of the model proposed and numerically investigated by (Liu and Bassler, 2006). The second one is our own new model.

A model based on activity

The basic idea of the evolutionary rule in this model is *active* nodes tend to lose links, static nodes tend to get links (Bornholdt and Rohlf, 2000). After the dynamics of an RBN falls onto an attractor, a node is defined to be active if it changes its value on the attractor at least once. Otherwise, the node is static (Bornholdt and Rohlf, 2000; Liu and Bassler, 2006). The full algorithm can be described as follows:

- (i) The initial RBN with uniform in-degree $k_i = k_0$ for all node $i = 1, 2, \dots, N$ is generated.
- (ii) A random initial state $\mathbf{x}(0)$ is chosen. Iterate RBN dynamics until a dynamical attractor is reached. In the chaotic phase, it is hard to find an attractor in a realistic number of time steps. To cope with this problem, we follow the procedure adopted in (Liu and Bassler, 2006). We set the maximum attractor period $T_{\rm max}$ which we try to find. If no attractor is found in the first $2T_{\rm max}+T'$ time steps, we regard the last $T_{\rm max}$ steps as an attractor. Here, we take $T_{\rm max}=1000$ and T'=100 for efficient numerical simulation. It seems that the value of $T_{\rm max}$ does not affect the result of numerical simulation as long as it is sufficiently large. Indeed, we checked that $T_{\rm max}=500$ also reproduces the essentially the same results.

Let Γ be the period of the attractor.

(iii) A node i is randomly chosen. Calculate its average activity A(i) over the attractor:

$$A(i) = \frac{1}{\Gamma} \sum_{t=T}^{T+\Gamma-1} \mathbf{x}_i(t), \tag{1}$$

where we assume that the attractor is reached at least after T time steps. If 0 < A(i) < 1, then the node is called active. Otherwise, it is called static.

(iv) If chosen node i is active, then one of its incoming links is removed randomly. If it is static, then it gains a new incoming link. The source node of a new link is chosen by following a probability distribution depending on the outdegree of nodes.

(v) Boolean functions are randomly regenerated. Here, we use the method called annealed model in (Liu and Bassler, 2006): a new Boolean function is generated randomly for every node.

(vi) Go back to step (ii).

The time scale of network topology change (one cycle of step (ii) to step (v)) is called epoch. (Liu and Bassler, 2006) numerically shows that this evolutionary algorithm with the uniform probability distribution in step (iv) drives RBN toward criticality.

A model based on local information transfer

The local rewiring rule of this model depends on information transfer associated with links. To quantify information transfer, we use local transfer entropy (Lizier et al., 2008). Transfer entropy is a measure of the direction and magnitude of information transfer between two stationary stochastic processes (Schreiber, 2000). Let X, Y be stationary stochastic processes. The transfer entropy from Y to X is

$$T_{Y \to X} = \sum_{x(t)^{(k)}, x(t+1), y(t)^{(l)}} p(x(t+1), x(t)^{(k)}, y(t)^{(l)})$$

$$\times \log_2 \frac{p(x(t+1)|x(t)^{(k)}, y(t)^{(l)})}{p(x(t+1)|x(t)^{(k)})},$$
 (2)

where x(t) and y(t) are values of X and Y at time t, respectively, $x(t)^{(k)} = (x(t), x(t-1), \cdots, x(t-k+1))$ and $y(t)^{(l)} = (y(t), y(t-1), \cdots, y(t-l+1))$. Namely, the amount of information transfer from Y to X is quantified as the reduction of uncertainty to predict the future value of X from the present and past values of itself when one knows the present and past values of Y. In the following, we only consider the case k=l=1.

The local transfer entropy considers the log-ratio at the right hand side of (2). (Lizier et al., 2008) shows that the local transfer entropy works as a filter detecting coherent structures in complex spatiotemporal dynamics. Since the log-ratio can take a negative value, we can define misleading information transfer by adopting the local transfer entropy for information transfer quantification (Lizier et al., 2008).

Consider a node i in an RBN and neighboring nodes j_1, j_2, \dots, j_{k_i} that have a link to i. The local transfer entropy from node j_m to i at time t is defined by

$$lte(j_m \to i, t) = \log_2 \frac{p(x_i(t+1)|x_i(t), x_{j_m}(t))}{p(x_i(t+1)|x_i(t))}, \quad (3)$$

where the conditional probabilities at the right hand side are calculated from the frequency of each tuple of values from the all pairs $(i, j_n), n = 1, 2, \dots, k_i$ over the attractor to which the RBN dynamics reaches.

The idea for the evolutionary algorithm based on local information transfer is *links with misleading information transfer should be deleted*. Here, we implement this idea by

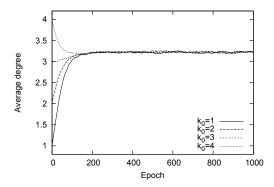

Figure 1: Time evolution of the average in-degree from different k_0 values in the adaptive network model based on local information transfer averaged over 100 trials. The system size is N=30.

replacing steps (iii) and (iv) in the model based on activity by the following (iii') and (iv').

(iii') Choose a node i and a time $T \leq t < T + \Gamma$ randomly. Calculate the local transfer entropy $lte(j_m \rightarrow i, t)$ for all $m = 1, 2, \cdots, k_i$.

(iv') If there is at least one link such that $lte(j_m \to i,t) < 0$, then the link with the smallest value of the local transfer entropy is deleted. If there are multiple such links, then one of them is chosen randomly and is deleted. If $lte(j_m \to i,t) \geq 0$ for all $m=1,2,\cdots,k_i$, then node i gets a new incoming link. The source node of a new link is chosen by following a probability distribution depending on the outdegree of nodes.

We numerically check that the model based on the local transfer entropy evolves toward criticality. Fig. 1 shows that time evolution of average in-degree from different k_0 values converges to a common value slightly above 3. Here, we adopt the uniform random choice of the source node of a newly added link at step (iv'). The deviation from the critical value 2 is rather large because of the finite size effect (N=30). Fig. 2 shows that the converged value of average in-degree approaches to the critical value 2 as N becomes larger. Indeed, it approaches algebraically to the criticality as we will see in next section (See Fig. 5).

Average in-degree evolves toward criticality in both adaptive RBN models. However, they have different stationary in-degree distributions as one can see in Fig. 3. On one hand, the stationary in-degree distribution for the model based on activity can be fitted by the Poisson distribution for all three link addition rules considered in next section. On the other hand, the width of that for the model based on local information transfer is strictly narrower than the Poisson distribution with the same average in-degree due to different local rewiring rules from those in the activity-based model.

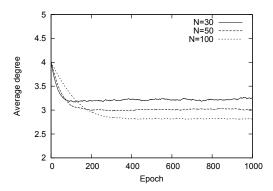

Figure 2: Time evolution of average in-degree for different system sizes N from the same k_0 value in the adaptive network model based on local information transfer. For each system size N, trajectories are averaged over 100 trials.

Main result

In this section, we present the formula relating local rewiring rules and stationary out-degree distributions. The theoretical result is tested against numerical simulation. The formula is derived in Appendix.

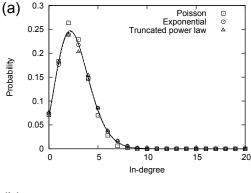

In the link addition part of the evolutionary algorithms described in section 2, the source node of a newly added link is chosen by following a probability distribution depending on the out-degree of nodes. Let $\sigma_{+,l}(e)$ be the probability that a particular node with out-degree l is chosen as the source of a new link given that the number of link increases at epoch e. In Appendix, we derive the following equation by analyzing the master equation describing time evolution of the out-degree distribution under the assumption that we can ignore the structure of networks except their degree distributions in the limit of large N:

$$\sigma_{+,l}^{s} = \frac{l+1}{Nz_{s}} \frac{P_{\text{out}}^{s}(l+1)}{P_{\text{out}}^{s}(l)},\tag{4}$$

where $\sigma^s_{+,l} = \lim_{e \to \infty} \sigma_{+,l}(e)$, z_s is the stationary average in-degree and $P^s_{\mathrm{out}}(l)$ is the stationary out-degree distribution. By (4), we can predict the link addition algorithm which produces the stationary out-degree distribution satisfying $P^s_{\mathrm{out}}(l) = P(l)$ for any given probability distribution P(l) with $\sum_{l=0}^{\infty} lP(l) = z_s$. Here, we study three representative cases.

Example 1 (Poisson distribution) If $P(l) = \frac{z_s^l}{l!} e^{-z_s}$, then $\frac{P(l+1)}{P(l)} = \frac{z_s}{l+1}$. It follows that $\sigma_{+,l}^s = \frac{1}{N}$ by (4). Thus, we expect the stationary Poisson out-degree distribution when we choose the source node of a newly added link uniformly at random.

Example 2 (Exponential distribution) If
$$P(l) = (1 - e^{-1/\kappa}) e^{-l/\kappa}$$
, where $\kappa = 1/\ln(1 + 1/z_s)$, then

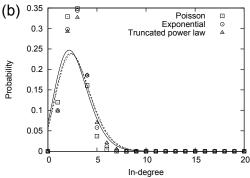

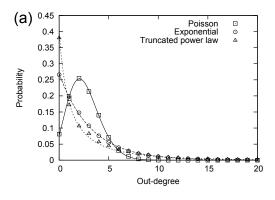

Figure 3: Stationary in-degree distributions for the two adaptive network models with different link addition rules introduced in section 2. (a) Results for the model based on activity. (b) Results for the model based on local information transfer. For every case, $N=200,\,k_0=4$ and the numerical stationary in-degree distribution is obtained by averaging in-degree distributions over 10000 epochs after 10000 initial transient epochs for a single trial. For reference, Poisson distribution with the same average degree is plotted for each case. Legends indicate different link addition algorithms described in section 3.

 $\frac{P(l+1)}{P(l)}=e^{-1/\kappa}.$ By (4), we have $\sigma_{+,l}^s=(l+1)\frac{e^{-1/\kappa}}{Nz_s}.$ The stationary exponential out-degree distribution is predicted when the source node of a newly added link is chosen in proportional to (l+1), where l is the out-degree of the node.

Example 3 (Truncated power law distribution) If

 $P(l)=C(l+1)^{-1}e^{-\lambda l}$, where C is a normalization constant and λ is determined by the equation $z_s=\sum_{l=0}^{\infty}lP(l)$, then $\frac{P(l+1)}{P(l)}=\frac{l+1}{l+2}$. By (4), $\sigma_{+,l}^s=\frac{(l+1)^2}{l+2}\frac{1}{Nz_s}$. If the source node of a newly added link is chosen in proportional to $\frac{(l+1)^2}{l+2}$, where l is the out-degree of the node, then the theory predicts that we have the stationary truncated power law out-degree distribution.

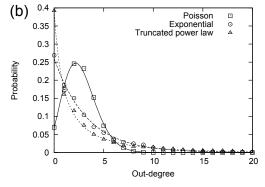

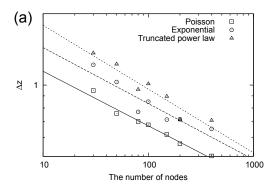

Figure 4: Stationary out-degree distributions for the two adaptive network models with different link addition rules. Theoretical lines are compared with the numerical distributions. (a) Results for the model based on activity. (b) Results for the model based on local information transfer. The parameters and the averaging procedure are the same as in Fig. 3.

We compare the numerical stationary out-degree distributions with the theoretical ones for both models of adaptive RBN in Fig. 4. In every case, the theoretical line agrees well with the numerical result. Fig. 5 shows that the stationary average in-degree approaches algebraically to the critical value 2 as the system size N increases irrespective of models and link addition rules though the speed of convergence is case-by-case. These results suggests that we can control the stationary out-degree distribution by (4) while keeping evolution toward criticality.

Discussion

In this paper, we have shown that we can control the stationary out-degree distribution of two adaptive RBN models that evolve toward criticality by modifying the link addition part of of the local rewiring rule. Only the information of neighboring nodes that have a link to a node to be removed is used for the link deletion part of the rule. In this sense, the link deletion part is informationally local. On the oth-

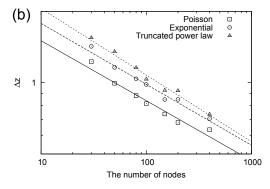

Figure 5: System size dependence of deviation from criticality $\Delta z=z_s-2$. (a) Results for the model based on activity. The slopes of the lines are -0.230 (real, Poisson), -0.236 (dashed, Exponential) and -0.269 (dotted, Truncated power law). (b) Results for the model based on local information transfer. The slopes of the lines are -0.253 (real, Poisson), -0.257 (dashed, Exponential) and -0.281 (dotted, Truncated power law). For every case, the stationary average indegree z_s is calculated by averaging average in-degrees over 10000 epochs after 10000 transient initial epochs in a single run from $k_0=4$.

er hand, the link addition part is informationally global: it inevitably needs global information because the source node of a newly added link is chosen from the set of all nodes in the whole system although the resulting structural change of network topology is local. Thus, there is asymmetry between the link deletion part and the link addition part in terms of information used. Our result indicates that evolution toward criticality can be achieved irrespective of the form of informationally global link addition part.

It has been suggested that real-world gene regulation networks have heavy-tailed out-degree distributions (Aldana et al., 2007). Assuming that the local rewiring rule studied in this paper is a good approximation to realistic network evolutionary process, the emergence of heavy-tailed out-degree distributions in real-world gene regulation networks cannot be directly associated with evolution toward

dynamical criticality. Rather, it could be a consequence of an unknown macroscopic constraint. Some models that evolve toward criticality and also generate a heavy-tailed degree distribution have been proposed so far (MacArthur et al., 2010; Torres-Sosa et al., 2012). In these models, mechanism to generate a heavy-tailed degree distribution would be involved implicitly in a whole evolutionary rule that takes into account global properties of the system. In contrast, the mechanism related to evolution toward criticality and that generates a given out-degree distribution can be separated explicitly in the adaptive network models studied in this paper.

If a macroscopic constraint forces a specific form of stationary out-degree distribution, then the underlying local rewiring rule is uniquely selected via (4). What macroscopic constraints can give rise to heavy-tailed out-degree distributions found in real-world gene regulation networks? Answering this question is out of the scope of the present paper and we leave it for future work.

Appendix

In this Appendix, we derive equation (4).

Let p_k be the probability that a chosen node with indegree k gets a new incoming link. The time evolution of in-degree distribution $P_{\rm in}(k,e)$ is described by the master equation $P_{\rm in}(k,e+1)=\left(1-\frac{1}{N}\right)P_{\rm in}(k,e)+\frac{1}{N}\left(p_{k-1}P_{\rm in}(k-1,e)+(1-p_{k+1})P_{\rm in}(k+1,e)\right)$ for $k\geq 1$ and $P_{\rm in}(0,e+1)=\left(1-\frac{1}{N}\right)P_{\rm in}(0,e)+\frac{1}{N}(1-p_1)P_{\rm in}(1,e).$

By equating $P_{\rm in}(k,e+1)$ to $P_{\rm in}(k,e)$, we obtain the condition for the stationary in-degree distribution $P_{\rm in}^s(k)$:

$$(1 - p_{k+1})P_{\text{in}}^{s}(k+1) = p_k P_{\text{in}}^{s}(k)$$
 (5)

for all $k \ge 0$. Here, we only assume that the existence of p_k and we leave the problem how to calculate p_k for a future work. It could be obtained under a certain mean-field approximation of the models. In the following, we concentrate on the analysis of the stationary out-degree distribution.

The time evolution of out-degree distribution $P_{\mathrm{out}}(l,e)$ follows the following master equation: $P_{\mathrm{out}}(l,e+1) = (1-q_{+,l}(e)-q_{-,l}(e)) P_{\mathrm{out}}(l,e) + q_{+,l-1}(e) P_{\mathrm{out}}(l-1,e) + q_{-,l+1}(e) P_{\mathrm{out}}(l+1,e)$ for $l \geq 1$ and $P_{\mathrm{out}}(0,e+1) = (1-q_{+,0}(e)) P_{\mathrm{out}}(0,e) + q_{-,1}(e) P_{\mathrm{out}}(1,e)$, where $q_{+,l}(e)$ is the probability that a node with out-degree l gets a new outgoing link at epoch e and $q_{-,l}(e)$ is the probability that a node with out-degree l loses an outgoing link at epoch e.

Put $\rho_+(e) := \sum_{k=0}^{\infty} P_{\mathrm{in}}(k,e) p_k$ and $\rho_-(e) := \sum_{k=0}^{\infty} P_{\mathrm{in}}(k,e) (1-p_k)$. Let $\sigma_{+,l}(e)$ be the probability that a particular node with out-degree l is chosen as the source of

a new link given that the number of link increases at epoch e and $\sigma_{-,l}(e)$ the probability that an outgoing link of a particular node with out-degree l is deleted given that the number of link decreases at epoch e. By definitions of ρ and σ , we have

$$q_{+,l}(e) = \rho_{+}(e)\sigma_{+,l}(e)$$
 (6)

and

$$q_{-,l}(e) = \rho_{-}(e)\sigma_{-,l}(e).$$
 (7)

We now introduce the configuration model (random networks with a specified degree distribution (Newman et al., 2001)) approximation: links are randomly shuffled while keeping the degree of each node at the end of each epoch. Then, we have

$$\sigma_{-,l}(e) = \frac{l}{Nz(e)} \tag{8}$$

in the limit of large N, where z(e) is the average in-degree at epoch e (which is equal to the average out-degree). Indeed, suppose that the chosen node at epoch e has in-degree k and it loses one of its incoming link. Noting that Nz(e) is the number of arcs, we find that the probability that there is a link from a node with out-degree l to a node with in-degree l is $1 - \left(1 - \frac{l}{Nz(e)}\right)^k \approx 1 - \left(1 - \frac{kl}{Nz(e)}\right) = \frac{kl}{Nz(e)}$ in the limit of large l. The probability of deletion of this link is l/k under the approximation. Thus, we obtain $\sigma_{-,l}(e) = \frac{kl}{Nz(e)}\frac{1}{k} = \frac{l}{Nz(e)}$.

As in the case with the stationary in-degree distribution, the stationary out-degree distribution $P_{\text{out}}^s(l)$ should satisfy

$$q_{-l+1}^s P_{\text{out}}^s(l+1) = q_{+l}^s P_{\text{out}}^s(l),$$
 (9)

for all $l\geq 0$, where $q_{+,l}^s=\rho_+^s\sigma_{+,l}^s$, $q_{-,l}^s=\rho_-^s\sigma_{-,l}^s$, $\rho_+^s=\sum_{k=0}^\infty P_{\rm in}^s(k)p_k,$ $\rho_-^s=\sum_{k=0}^\infty P_{\rm in}^s(k)(1-p_k)$ and $\sigma_{+,l}^s$ and $\sigma_{-,l}^s$ are stationary values for corresponding epoch-dependent quantities, respectively. Since $p_0=1$, we have

$$\rho_{+}^{s} = \rho_{-}^{s} \tag{10}$$

by (5). Substituting the stationary analogue of (8) and (10) into (9), we obtain equation (4)

$$\sigma_{+,l}^s = \frac{l+1}{Nz_s} \frac{P_{\text{out}}^s(l+1)}{P_{\text{out}}^s(l)},$$

where z_s is the stationary average in-degree.

Random Fuzzy Networks

Octavio B. Zapata¹ and Carlos Gershenson¹

¹Instituto de Investigaciones en Matemáticas Aplicadas y en Sistemas, UNAM, México, D.F. 01000 ocbzapata@gmail.com cgg@unam.mx

Introduction

No model can be considered effective if fundamentally it is more complicated than what it's trying to represent. However, extreme simplification may potentially overlook important non-primary features, or even neglect the possibility to represent ambiguous or unclear observations. Therefore, achieving a balance between parsimonious and detailed models is of utmost importance for science and engineering.

Over the past few decades, random Boolean networks (RBNs) (Kauffman, 1969) have become popular models for genetic regulatory networks. This popularity is associated with the fact that RBNs are very general models. No functionality or structure is particularly assumed when constructing them. However, the Boolean idealization has been constantly criticized based on the assumption that constraining the variables of the model to have only two possible values (0 and 1) entails a loss of dynamical information in the analysis of real gene expression data.

Boolean and Continuous Models

To randomly generate a network of dynamically interacting agents is very convenient for modeling systems where the underlying structure or performance is not yet explicitly recognized. The RBN model consists of n nodes, each of which have k randomly chosen input links, that determine its value $\sigma_i(t)$ at time step t from the set $\Sigma = \{0,1\}$ where $i=1,\ldots,n$. At time t+1 the state $\sigma_i(t+1)$ is completely determined by a randomly chosen Boolean function $f_i:\Sigma^k\to\Sigma$ from its k inputs at a previous time step, i.e. $\sigma_i(t+1)=f_i(\sigma_{i_1}(t),\ldots,\sigma_{i_k}(t))$. These functions can be computed via a lookup table —one for each function.

There have been several critiques for both, the Boolean idealization (Yingjun et al., 2007; Wittmann et al., 2009), and the temporal discretization (Bagley and Glass, 1996; Kappler et al., 2003) of RBNs. On the other hand, methods that justify the Boolean case have been proven effective, e.g., in Shmulevich and Zhang (2002); Karlebach (2013).

Multi-state approaches (Wuensche, 1998; Solé et al., 2000; Wittmann and Theis, 2011) emerged from the consideration that in some natural systems, the discreteness of

the actions performed at individual levels is well defined and thus, the dynamic assumption from a discrete model is fairly plausible; nevertheless, transitions from one state to another may not be sufficiently sharp for being represented by Boolean variables. Multi-valued variables that range over multiple (not only binary) states enhance the capability of the model to accurately portray gradual changes on the dynamic individual behavior of the system.

Random Fuzzy Networks

We extended the classical Boolean model (Kauffman, 1969; Wuensche, 1998; Aldana et al., 2003; Gershenson, 2004) by using concepts from fuzzy logic (Zadeh, 1965). The number of possible states s in which a node may be, vary according to the parameter $\phi \in [0,1]$. A random fuzzy network (RFN) is a RBN where the initial state of each node can take values from the set $\Sigma = \{1, s-2/s-1, s-3/s-1, \ldots, 0\}$ whereas s depends on ϕ . The fuzzyness of the state space—and therefore of the net—can be controlled by ranging ϕ along the interval [0,1]. More specifically, when $\phi=0$, we have the Boolean case where s=2. Otherwise, if $\phi=1$, then $s\to\infty$ and states can take values from all rational numbers between zero and one. We call s the base of the net. Whichever base may be achieved choosing the right ϕ .

Each lookup table in a RBN can be fuzzyfied, representing it in terms of combinations of AND, OR, and NOT and using Zadeh's operators (MIN, MAX, and 1-x, respectively). In this way, depending only on the diversity of the initial states, the same RFN can go from Boolean to continuous.

We introduce the concept of a *family of attractors*, to group attractors with the same transition schema. This concept helps us to study the state space dynamics of RFNs, regardless of its base. Specific state values are not taken into account. A family represents in which *direction* the states within an attractor change, i.e., a node state either goes up (represented by 1) if $\sigma_i(t) < \sigma_i(t+1)$, down(-1) if $\sigma_i(t) > \sigma_i(t+1)$ or stays(0) if $\sigma_i(t) = \sigma_i(t+1)$. All attractors on a particular family have the same length. Different attractors might belong to the same family. In particular,

steady states (point attractors) are all members of the family, e.g., (0, ..., 0). Transitions space size (3^n) is fixed for all ϕ .

Preliminary Results

The extended RFN model was implemented on Java virtual laboratory RBNLab (Gershenson, 2005). We explore the state space dynamics on ensembles $\mathbf{F}(n,k,\phi)$ of fuzzy nets with n=10,20,100 and $k=1,\ldots,5$. Five different ϕ values were chosen, giving base numbers s equals to 2,4,8,16 and ∞ , respectively. The number of initial states explored was arbitrarily bounded because as we let $\phi \to 1$, the size of the state space (s^n) increases proportionally to the base—and it rapidly becomes intractable. We do not consider significant the results for n=10 ensembles. On the other hand, due to the potentially astronomical amount of system states for n=100 nets, results might be biased because with a high probability one does not explore a representative part of the state space.

As shown in figure 1, the average number of attractors $\langle att \rangle$ found for n=20 RFNs, increases exponentially for s>2. The average number of families $\langle fam \rangle$ also increases but the growth-rate seems to be linear. For $\langle att \rangle$, standard deviations were maximal on continuous ($\phi=1$) ensembles, and for $\langle fam \rangle$ they were when k=5. We did not observe a significant increase on $\langle fam \rangle$ when data representation goes from Boolean to continuous. This result suggests that in the process of discretization there is few loss of information (families), and hence we can assert that fuzzy networks are capable to achieve a significant degree of complexity reduction –via its ϕ parameter. Therefore, we conclude by saying that the use of Boolean models for coarsely studying the discrete dynamics of real-valued observations is further supported.

Structure and dynamics affect the controllability of complex systems: a Preliminary Study

Complex systems are typically understood as large nonlinear multivariate systems. Their organization and behavior are commonly modeled by representations such as graphs and automata networks. Graphs, where nodes representing variables lack intrinsic dynamics, capture the *structure* or organization of complex systems. The simplest way to study multi-variate *dynamics*, is to allow network nodes to have states and update them with automata; for instance, Boolean networks (BN) are canonical models of complex systems and exhibit a wide range of dynamical behaviors [1].

The structure of networks has provided many insights into the organization of complex systems [2]. The success of this approach is its ability to capture the organization of complex systems, and how it changes in time (network evolution) without explicit dynamical rules for node variables. As the field matures, however, there is a need to move from understanding to controlling complex systems. This is particularly true in systems biology and medicine, where increasingly accurate models of biochemical regulation have been produced [3]. More than understanding the organization of biochemical regulation, we need to derive control strategies that allow us, for instance, to move a mutant cell to a wild-type state [4], or revert a mature cell to a pluripotent state [5]. Towards these goals, a question of central importance remains: How well does network structure represent the multivariate dynamics of the underlying complex system, especially from the point of view of control?

Network controllability aims precisely to identify a minimal set of *driver variables* (a.k.a. driver nodes) from the structural network, which can fully control system dynamics—i.e. drive system dynamics to any state-space configuration [6]. *Structural controllability* is an influential method to derive driver variables, using only structural properties of the system without any consideration of its dynamical details [7]. It has been used to suggest, for instance, that biological systems are harder to control than social systems [8]. However, applications of structural controllability have been heavily critiqued due to its stringent assumptions [9].

Here we explore the relationship between network structure and controllability through the analysis of dynamical ensembles of BN. The control problem for general BN is computationally intractable (NP-hard) [10]. Simplification techniques, such as structural controllability or those based on dynamical redundancy [4], are thus highly desirable. The BN studied here are discrete dynamical systems $\mathcal{X} = \{x_i\}$ of N Boolean variables $x_i \in \{0,1\}$ that are updated synchronously according to deterministic logical functions. The structural network specifies all directed pairwise interactions $\{e_{ij}\}$ which indicate when variable x_i is an input for the logic of x_i . At time t, the network is in a configuration X^t , which is the vector of all variable states $(x_i(t))$ at time t. The overall dynamics of temporal sequences of network configurations can be represented by the state-transition graph (STG). In this graph, each node is a configuration X^t of the BN and each directed edge is a transition from X^t to X^{t+1} . Thus, the STG fully describes the 2^N possible configurations and transitions in the network's dynamical landscape.

We study the control due to a subset $\mathcal{D}\subset\mathcal{X}$ of driver variables as instantaneous perturbations to the variable's state. To capture all possible dynamically allowable trajectories due to controlled interventions on \mathcal{D} , we introduce the *controlled state transition graph* (CSTG $_{\mathcal{D}}$). The CSTG $_{\mathcal{D}}$ is an extension of the STG where additional edges connect a configuration to each of its $2^{|\mathcal{D}|}-1$ perturbed counterparts. The network is fully controllable if a trajectory exists between every pair of configurations; for BN this is equivalent to requiring the CSTG $_{\mathcal{D}}$ to be strongly-connected.

We extend this binary notion of controllability by tallying the fraction of configurations that are controlled by driver set \mathcal{D} . Given a specific configuration X_k , the fraction of reachable configurations $r_{\text{CSTG}_{\mathcal{D}}}(X_k)$ is the number of other configurations reachable on graph $\text{CSTG}_{\mathcal{D}}$ via a directed path starting from X_k , normalized by 2^N-1 . The mean fraction of reachable configurations is then given by $\overline{R} = \langle r_{\text{CSTG}_{\mathcal{D}}}(X_k) \rangle_k$, where $k=1\dots 2^N$. It measures the fraction of configurations which are on average reachable by controlling the variables in \mathcal{D} . The mean fraction of controlled configurations is $\overline{C} = \langle r_{\text{CSTG}_{\mathcal{D}}}(X_k) - r_{\text{STG}}(X_k) \rangle_k$. It measures the average fraction of controlled configurations by discounting those transitions which would have naturally

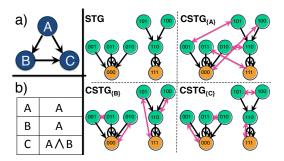

Figure 1: a) FeedForward network motif structure with dynamics given by the rules in b) give rise to the State-Transition Graph (STG). Each of the singleton sets $\{A\}$, $\{B\}$, and $\{C\}$ are used as driver variable sets to produce the Controlled STGs (CSTG $_{\mathcal{D}}$) shown.

occurred due to the uncontrolled dynamics of the network. A fully controlled network must have $\overline{R}=1.0$, but partially controlled networks will vary in [0,1].

We start by characterizing the entire ensemble of possible BN dynamics for the N=3 variable Feed-Forward network motif [11] shown in Figure 1a. For each network structure, there are $L = \sum_{i} 2^{k_i}$ possible transition rules, where k_i is the in-degree of variable x_i . In this case, the full ensemble consists of $2^L = 2^6 = 64$ distinct networks; the logic of one is depicted in Figure 1b. This figure also depicts its STG and the CSTG $_{\mathcal{D}}$ for various driver sets \mathcal{D} . If we additionally remove all variable transition functions that refer to tautologies, contradictions, and functions always controlled by a single input (fully canalizing [12]), we obtain a smaller Non-trivial ensemble. The controllability analysis for both ensembles is shown in Figure 2. Notice that structural controllability analysis predicts that variable A is capable of fully controlling the network. However, this driver variable $(CSTG_{\{A\}})$ fails to control a large majority of the possible BN. Even pairs of variables cannot fully control all networks $(\overline{R} < 1.0)$; to guarantee full control for every network, all three variables need to be driven.

This simple example highlights the tenuous relationship between structure and dynamics for complex systems, and the implications for understanding and characterizing their control. This work has been extended in four significant ways [13], and will be showcased at the conference: (1) analysis of several more network motifs; (2) extend our measures of partial control to the more biologically relevant concept of attractor control (since all non-attractor configurations are transients); (3) study the space of random BN (such as Erdos-Renyi structural networks with transitions parameterized by in-degree and bias) to establish that similar results hold as the systems are scaled up; (4) study models of biochemical regulation such as the segment polarity generegulatory BN of Drosophila melanogaster [14], the control of which is known [4]. These studies show how the structure-only analysis of complex systems tends to fail to

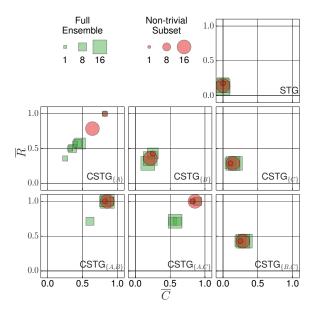

Figure 2: Measures \overline{R} and \overline{C} for the Full Ensemble of 64 BN (green squares and red circles) with structure given by the Feed-Forward network motif shown in Figure 1, as controlled by various combinations of driver variables. The Non-trivial subset is highlighted by red circles.

properly characterize their full or partial controllability. Additionally, we lay the groundwork for understanding which restrictions must be enforced on the transition functions of BN, such that structure may suffice for predicting controllability. Our full study and analysis has been submitted for publication [13].

Evolving Spiking Networks for Turbulence-Tolerant Quadrotor Control

David Howard¹ and Alberto Elfes¹

¹CSIRO, Autonomous Systems Program, 1 Technology Court Pullenvale, QLD 4069 Australia david.howard@csiro.au

Abstract

We investigate the automatic development of robust quadrotor neurocontrollers based on spiking neural networks. A self-adaptive evolutionary algorithm is used to generate high-utility topology/weight combinations in the networks, and a simple synaptic plasticity mechanism provides some degree of in-trial adaptation. Incremental evolution gradually increases the severity of environmental conditions that the agent can successfully handle. Results compare the spiking networks to tuned Proportional/Integral/Derivative controllers and feedforward neural networks for waypoint-holding experiments in varied atmospheric conditions. It is shown that the spiking controllers are able to maintain a closer distance to the waypoint than the comparative controllers, and more effectively deal with more challenging environmental conditions.

Introduction

The control of quadrotors in outdoor scenarios is a difficult task as both the agent and environment are highly dynamic. Traditional controllers, e.g. Proportional/Integral/Derivative (PID) (Minorsky, 1922), are still widely used in such scenarios, yet they are restricted to linear control and often require hand-tuning to achieve acceptable performance. Recent research has shown that nonstandard nonlinear controllers such as evolved feedforward neural networks (Rumelhart and McClelland, 1986) can automatically generate controllers that provide performance enhancements (Shepherd and Tumer, 2010).

Due to the dynamical nature of the task, *stateful* neural network representations may make suitable controllers due to their ability to (i) generate highly nonlinear action sequences through internal network dynamics, and (ii) harness latent information that may be found in temporally sequenced states (Maass and Zador, 1999). In this paper, we focus on the evolution of stateful spiking neural controlelrs (Gerstner and Kistler, 2002) for outdoor scenarios.

Spiking control systems offer a plethora of benefits, including temporally-sensitive neuron memory, the ability to perform highly nonlinear state-action mappings which may be demanded by the platform, and relatively straightforward

mapping to power-efficient pulsed hardware implementations (important when considering future onboard control). Spiking networks are biologically plausible representations and as such permit numerous extensions based on neuroscientific principles — a simple model of synapse-level Hebbian plasticity (Hebb, 1949) here provides in-trial adaptivity through spike timing coincidences. Action calculation is also based on spike coincidences (at the output neurons).

A Genetic Algorthm (GA) (Holland, 1975) is used to automatically generate high-performance controllers by seeking beneficial network compositions — the weights and topological placement of the synapses, along with neuron numbers and types, are all under GA control. Self-adaptive mutation provides the GA with as much freedom as possible by allowing specific subcomponents of each network to mutate at varying rates.

Despite numerous recorded successes when spiking networks are used to control ground-based robots (e.g., (Floreano et al., 2003a; Rocke et al., 2007)), to date no spiking neuro-evolution has been carried out on highly dynamic flying platforms. We wish to investigate the benefits of pairing a dynamic, stateful controller representation with a problem that displays the same properties. Our hypothesis is that the properties of the spiking networks make them especially suited to the control of dynamic agents in dynamic scenarios. To test this hypothesis we incrementally evolve a population of spiking controllers in increasingly challenging wind conditions and compare performance to a hand-tuned PID controller and evolved Multi-Layer Perceptron (MLP) neural networks (Rumelhart and McClelland, 1986). The controllers must keep the quadrotor as close to a pre-defined waypoint as possible, in spite of prevaling wind conditions.

The main contribution of this paper is the first use of evolutionary computing to generate spiking quadrotor neuro-controllers. We additionally provide evidence that even simple plasticity schemes can be a useful provider of adaptation in dynamic scenarios, and introduce a novel action encoding scheme that permits the spiking networks to operate at a higher frequency than those using traditional e.g., rate-based encoding schemes.

Background

Spiking Neuro-Controllers

Spiking neural networks are a bioinspired information processing paradigm based on studies of neural structure and activity in the brain. A number of neurons are linked via unidirectional, weighted connections. Each neuron has a measure of excitation (membrane potential) and communicates to other neurons via voltage spikes. A neuron spikes when its membrane potential exceeds some threshold, which typically requires a cluster of spikes arriving at the neuron within a short time period. Produced spikes are received by all forward-connected neurons. As membrane potential provides implicit memory, spiking networks are able to produce temporally dynamic activation patterns (Maass, 1997). Saggie-Wexler et al. (2006) highlight that this property makes them particularly suited for temporal problems such as robot control as steady-state errors and unmodelled dynamics can be accounted for. Recent studies in cognitive science highlight the importance of dynamic processes in memory and learning (Buzsaki, 2006).

Non-evolutionary approaches to spiking robot control include dynamic learning of navigation behaviour via conditioning (Helgadottir et al., 2013) and real-time training of neuro-controllers based on resovoir computing (Burgsteiner, 2005). Wiles et al. (2010) creates biologically plausible models of a rat's brain via self-organised learning for phototaxis. Commonalities between the studies include reports of adaptive learning, high performance in dynamic environments, and fast-changing nonlinear behaviour generation.

Evolutionary Robotics (Nolfi and Floreano, 2001) involves the use of evolutionary algorithms to design robot controllers. Neural networks are frequently used in such a setting as they are especially amenable to evolutionary search for beneficial compositions of connection weights and network topology — generally termed neuro-evolution - and have been shown to generate high-performance controllers. Hagras and Sobh (2002) evolve spiking networks for online robot control. Full topology-plus-weight evolution is used for both monolithic (Clune et al., 2009) and ensemble (Howard et al., 2010) controllers. Of particular interest is the work of Dario Floreano's group, who produce compact controllers for ground-based robots (e.g., Floreano et al. (2003a)), and evolve a spiking controller for an autonomous blimp (Floreano et al., 2003b). They demonstrate that even simple spiking representations can effectively process temporal state information.

Hebbian plasticity (Hebb, 1949) is thought to provide the brain with the properties of adaptation and self-organisation. Mechanistically, if one neuron can be said to have caused the subsequent firing of another neuron within a short time window, the connection strength between the two neurons increases and more strongly correlates their future activity. The reverse rule causes weight decay if the postsynaptic neuron fires first. Plasticity can provide unsuper-

vised in-trial learning, and as such is a valuable inclusion in robotic control systems that can be directly implemented in most spiking network models. Previous research by Wiles et al. (2010) demonstrates high performance of plastic networks in a frequency discrimination task in dynamic environments. Florian (2005) use a combination of STDP and global reward signals to effectively handle environmental uncertainty. Howard et al. (2014) show expedient adaptive re-organisation to recover from movement of the reward signal in the T-maze (Blynel and Floreano, 2003).

Evolving Rotorcraft Controllers

Evolution of rotorcraft controllers is difficult as finding an initial fitness gradient can be tricky — much of the network search space leads to controllers that crash the platform. Population seeding is often used to remedy this: three main examples include (i) incremental approaches (Hoffmann et al. (1998) generate fuzzy PID controllers for helicopter control), (ii) seeding with known successful controller parameters (De Nardi et al. (2006) evolve simple fixed-topology neurocontrollers that initially mimic PID control, and eventually evolve to outperform them; similar results are shown by Shepherd and Tumer (2010) for hierarchical waypoint-following tasks), and (iii) ensuring non-divergent networks in the initial population (Phillips et al. (1996) control a full-sized helicopter by evolving fuzzy modular controllers in a custom architecture based on how a human pilot flies a helicopter). All report higher performance when using seeding. Koppejan and Whiteson (2009) combine evolutionary algorithms and reinforcement learning for noisy hovering tasks similar to those we are interested in. Hovering tasks have been solved using Genetic Programming (Koza, 1992), e.g. by Dracopoulos and Effraimidis (2012).

Justification of our research methodology and approach is based on the knowledge that (i) spiking networks have previously been shown to be effective controllers for dynamic robotics tasks, (ii) evolved stateless neural networks (and other representations) have made promising candidate controllers for rotorcraft, and (iii) incremental approaches have shown to be beneficial given the difficulty of locating an initial fitness gradient. There is therefore some precedent to believe that incrementally evolved spiking quadrotor controllers will provide performance benefits when compared to stateless or traditional control schema in dynamic scenarios.

The System

To clarify the nomenclature that will be used herein: An *experiment* lasts for 500 evolutionary generations and focuses on a single controller in a single task. A *task* is a specific wind configuration in which the platform is tested. Each *generation*, 25 new controllers are created, trialled on the task, and assigned a fitness value. Each *trial* consists of a maximum of 300 timesteps and ends with a fitness value

being assigned. Each *timestep* begins with the current state being processed by the controller and ends with the resulting action being carried out and the simulator state updated. The state of the system is captured every 50 generations and used to generate the results. Fifteen experimental repeats for each controller type are used to create statistics and averages.

An incremental approach is used to focus the evolutionary search in areas that proved fruitful in similar, earlier tasks. This is designed to offset the poor initial fitness gradient caused by the catastrophic nature of failures, coupled with the fact that large portions of the network space were found to produce invalid controllers. For the first task, the population of networks is randomly generated with five hidden layer neurons. For subsequent tasks, the best 100 networks from the previous task are used as the initial population — each network is mutated at their current rates before being trialled on the problem.

Experimental Setup

We compare the ability of each controller type (spiking network, MLP, PID) to handle a series of four dynamic tasks. The QRSim (De Nardi, 2013) simulator was used as it models the physical platform we intend to eventually deploy the controllers on, and provides a high-fidelity wind model.

The quadrotor is an Asctec Pelican, whose flight performance is captured through system identification. Sensors and motors are subject to realistic normally-distributed noise; pertinently the GPS is modelled in detail accounting for factors such as varying numbers of available satellites and errors associated with transmission through various atmospheric layers. The quadrotor's software layer — which transforms desired control inputs into rotor RPM — is qualititively modelled to reflect the real platform.

All tasks take place in a three-dimensional arena with boundaries for each axis at $x_{min}/y_{min}/z_{min}$ =-10, $x_{max}/y_{max}/z_{max}$ =10 (z_{min} is ground level). At the start of a trial, the quadrotor in initialised at target waypoint W with position x=0,y=0,z=0 and the three control inputs are set to neutral (pitch θ =0°, roll ϕ =0°, thrust T=0.59) — see figure 1(a). Due to the complexity of the task, yaw is decoupled and stabilised to face North by a simple proportional controller. An image captured partway through a trial is shown in figure 1(b).

The quadrotor must stay as close as possible to W for 30 seconds of flight time — a control rate of 10Hz gives a maximum of t_{max} =300 timesteps per trial. At each timestep, the controller receives the noisy GPS-estimated difference between the quadrotor's estimated position and W in three dimensions, given as Δx_t , Δy_t , and Δz_t (units in metres, transformed to quadrotor body coordinates). Control inputs θ , ϕ , and T are calculated and passed to the simulator, which fuses them with the current yaw rate and wind state, and updates the platform state. Fitness f follows equation 1. Lower fitness indicates better hovering behaviour.

$$f = \sum_{t=0}^{t < t_{max}} \left(abs(\Delta x_t) + abs(\Delta y_t) + abs(\Delta z_t) \right)$$
 (1)

Violating a boundary causes trial termination and penalises the controller with a final fitness of $30\times$ the remaining number of timesteps in the trial, which is added to it's current fitness and is used as a pressure to generate controllers that can keep the quadrotor airborne.

We additionally compare the adaptation of the controllers to the task by recording the first generation that each experiment creates a *valid* controller G_{val} (that never violates a boundary), as well as the first generation with a controller that keeps the quadrotor within (i) 1.5m $(G_{1.5})$, (ii) 1m $(G_{1.0})$, and (iii) 0.5m $(G_{0.5})$ of the waypoint in every axis throughout the trial. If some of these criterea are not met by the end of the experiment, they are set to the maximum number of generations.

The tasks are as follows: (i) 1m/s steady wind, (ii) 1m/s gusting wind, (iii) 3m/s gusting wind, and (iv) 5m/s gusting wind, all with a general northerly direction. Wind is modelled as a noisy time-varying vector which is applied to the quadrotor centre of gravity. For steady wind, the magnitude of the vector is normally distributed around the mean values. Gusting wind follows a more in-depth model based on the Dryden spectrum, providing a plausible and challenging dynamic turbulence model — Liepmann (1952) provides full implementation details.

Spiking Controller

Leaky Integrate and Fire (LIF) (Gerstner and Kistler, 2002) networks are used as spiking controllers — three layers of neurons are connected by numerous weighted connections (weights constrained [0-1]), which can be recurrent within the hidden layer only. Neurons are either excitatory (transmit voltages $V \ge 0$) or inhibitory (V < 0).

On network creation, the hidden layer is populated with 5 hidden layer neurons, whose types are intitially excitatory with P=0.5, otherwise they are inhibitory. Each possible connection site is initially likely to have a connection with P=0.5, and all connections are weighted uniform-randomly in the range [0-1].

During activation, stimulation by incoming voltage alters the membrane potential y,y>0, which by default decreases over time. Surpassing a threshold y_{θ} causes a spike to be transmitted to all forward-connected neurons. The amount of voltage sent is equal to the weight of the connection, multiplied by -1 if sent from an inhibitory neuron. Immediately after spiking, the neuron resets its membrane potential to c. The membrane potential of a neuron at timestep t+1 is given in equation 2; equation 3 shows the reset formula.

$$y(t+1) = y(t) + (I + a - by(t))$$
 (2)

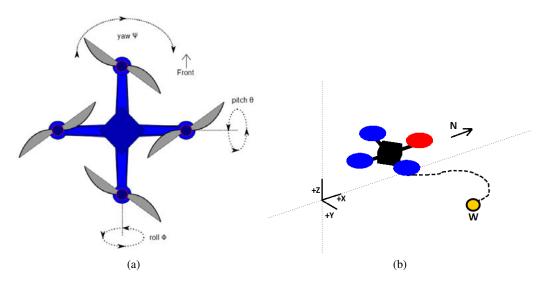

Figure 1: (a)Top-down view of the quadrotor showing pitch, roll and yaw. Thrust controls the homoegenous RPM of the rotor blades. Arrows show the direction of negative change.(b)The test environment, zoomed to show the quadrotor. The quadrotor (red rotor front) must stay as close as possible to the waypoint W (yellow circle). A sample path is shown (dashed line).

If
$$(y(t) > y_{\theta}) y(t) = c$$
 (3)

Here, y(t) is the neuron membrane potential at timestep t, I is the input voltage, a is a positive constant and b is the leak constant. A spike sent between two hidden layer neurons is received n (n > 1) steps after it is sent, where n is the number of neurons between the sending neuron and receiving neuron. A sample network is shown in figure 2. Parameters are a = 0.3, b = 0.05, c = 0.0, $y_{\theta} = 0.6$

A simple discrete-time linear model of plasticity is used to dynamically reconfigure the connection weights during the lifetime of the agent. The instantaneous weight w of a given connection is altered if it's two connected neurons spike in subsequent timesteps; no change occurs if both spike concurrently as causality cannot be implied. The sign of the weight change depends on which neuron — presynaptic (weight increase) or postsynaptic (weight decrease) — fires first, Δw =0.05 (experimentally determined). After a trial, each connection is reset to it's starting weight.

At a given timestep, three input neurons receive Δx_t , Δy_t , and Δz_t , which are scaled to the range [0,1]. The network sequentially updates it's input, hidden, and output layer neurons. Spike coincidences are checked and the plasticity rule applied to any affected synapses. Three pairs of output neurons control the commanded pitch θ (θ_{min} =-45°, θ_{max} =45°), roll ϕ ,(ϕ_{min} =-45°, ϕ_{max} =45°) and thrust T (T_{min} =0, T_{max} =1). If the first neuron spikes and the second does not, the relevant control variable is increased by 0.05 of it's total range (experimentally determined). If only the second neuron spikes, the control variable is decreased by the same amount. If neither or both neurons spike, the control variable is unchanged. Note that with this action en-

coding, (i) the total time to traverse the entire range of each variable is 4.4s, and (ii) the controller does not need to wait for multiple network processing steps before generating an action as with rate-based schemes. This will become more important in future experimentation with onboard control.

Comparitive Controllers We compare the spiking controllers (stateful, nonlinear) to PID controllers (stateful, linear) and MLP networks (stateless, nonlinear).

PIDs are chosen as they are a common provider of closed-loop control. The PID is hand-tuned experimentally from ground-truth readouts from the simulator. Full PIDs are used for attitude and altitude control. The provided PIDs have more stringent pre-defined operating limits of $\pm 20^{\circ}$ for θ and ϕ and, due to their linearity, do not operate well outside of these bounds. More of the flight envelope is therefore available to the spiking/MLP controllers $(\pm 45^{\circ})$.

MLPs are a challenging benchmark that have previously shown promising results for quadrotor control. Sigmoidal activation functions are used and each hidden layer neuron has a random bias between 0 and 1. Rather than mapping continuous outputs to continuous angles/thrust, a similar pairwise encoding to the spiking networks is used, i.e., increase in a given variable occurs when the output of the first neuron is >0.2 more than that of the second neuron. Initial experimentation (not shown) compared the chosen encoding to a standard continuous-output interpretation and indicated no significant differences between the two encodings, possibly due to the compression effect of the sigmoid function around midrange outputs. Plasticity is not used as no spiketime information is available.

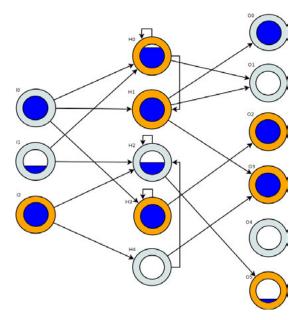

Figure 2: Showing a sample spiking network during activation. A neuron may be excitatory (orange) or inhibitory (grey), and has a membrane potential (centre circle). Membrane potential may build through a number of timesteps, eventually surpassing a threshold and emitting a spike (filled inner circle), before resetting (empty inner circle). Three input neurons take the differences in x, y, and z in the body frame between current position and target position. The six output neurons are paired; each pair controls either pitch, roll, or thrust. Actions are based on the presence or absense of instantaneous spikes at that timestep.

Genetic Algorithm

Per generation, following controller evaluation, the population is ranked based on fitness. The worst 25 networks are deleted. Children are then created up to the population limit of 100 by inverse-fitness-proportionate selection of a candidate parent, which is copied and probabilistically mutated before being inserted into the population. Crossover is omitted as — for these experiments — sufficient solution space exploration is obtained via a combination of weight and topology mutations; a view that is reinforced in the literature (e.g., by Rocha et al. (2003)).

Each network has it's own self-adaptive mutation rates, which are initially seeded uniform-randomly in the range [0,0.3] and mutated as with an Evolution Strategy (Rechenberg, 1973) as they are passed from parent to child following equation 4. This approach is adopted as it is envisaged that efficient search of weights and neurons will require different rates, e.g., adding a neuron is likely to impact a network more than changing a connection weight, so less neuron addition events than connection weight change events are likely to be desirable.

$$\mu \to \mu \ exp^{N(0,1)} \tag{4}$$

The genome of each network comprises a variable-length vector of connections and a variable-length vector of neurons, plus the mutation rates themselves. Different parameters govern the mutation rates of connection weights (μ) , connection addition/removal (τ) , neuron addition/removal (ω) , and neuron type change (ζ) . For each comparison to one of these rates a uniform-random number is generated; if it is lower than the rate, the variable is said to be satisfied at that allelle. During GA application, for each connection, satisfaction of μ alters the weight by ± 0 -0.1. Each possible connection site in the network is traversed and, on satisfaction of τ , either a new connection is added if the site is vacant, or the pre-existing connection at that site is removed. ω is checked once, and equiprobably adds or removes a neuron from the hidden layer if satisfied. ζ is checked once per neuron, and changes a neuron's type from excitatory to inhibitory (or vice versa) if satisfied. New neurons are randomly assigned a type, and each connection site on a new neuron has a 50% chance of having a connection. New connections are randomly weighted between 0 and 1.

Results

In the following comparisons, statistical significance is assessed using twin-tailed t-tests. Results are significantly different when p<0.05. Initial experimentation on the first task justifies the use of plasticity. Compared to identically-evolved spiking networks with static connection weights, plastic networks have significantly better average best fitness (50.32 for plastic networks vs 55.21 for non-plastic), as well as faster creation of controllers that attain $G_{1.5}$ and $G_{1.0}$ (average 6.7 vs 18.3 generations), and $G_{0.5}$ (average 9.3 vs. 24.5 generations).

Performance

Figure 3(a) shows the performance of each controller through all experiments. We note that MLP networks find the transition between environments to be more challenging than spiking networks (larger initial increases in fitness before recovery). In the final task, spiking networks start to pull away from the MLP and PID controllers. A gradual upwards trend in final fitness values reflects the increasing challenge of the tasks. Table 1 reveals that, for the first three tasks, both MLP and spiking controllers have significantly better final fitness than PIDs. For the final task, spiking controllers have significantly better final fitness than MLPs and PIDs. Average fitness values are strongly influenced by the number of valid controllers produced per generation, and reflects the ability of the GA to create child networks that inherit useful features from highly-fit parent networks. This ability may be useful for future on-line/on-board evolution. Spiking controllers are found to be more "evolvable" in this

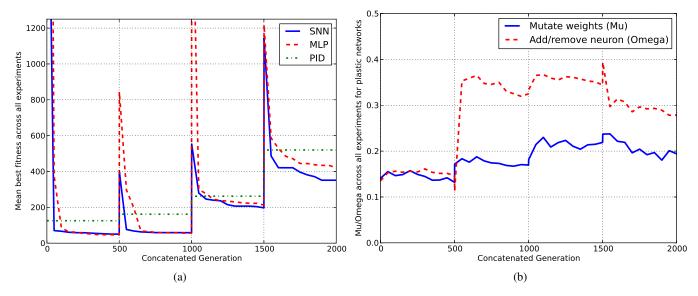

Figure 3: (a) Fitness recovery between tasks. MLPs suffer from greater initial fitness spikes and take longer to recover. (b) Mutation rates for connection weights and frequency of node addition/removal events for spiking networks across tasks. Note (i) the significant variance of final used mutation rates for each task, (ii) the gradual increase in weight mutation and neuron addition/removal events in response to more challenging environments. MLPs display similar trends.

sense — for the final two tasks spiking networks have significantly better average fitness than MLPs. Related to this, spiking networks were found to be more quickly able to evolve controllers that displayed the ability to hover. For all tasks, spiking networks were significantly faster than MLPs at attaining $G_{1.5}$, and for the first two tasks at attaining $G_{1.0}$ and $G_{0.5}$. Only spiking networks achieve $G_{0.5}$ in task 3, and no controller type achieves $G_{0.5}$ in task 4. Performance differences in all cases are attributed to the ability of the spiking networks to handle temporal phenomena (all other experimental parameters were identical, network action encodings were made as similar as possible).

We additionally note that in tasks 3 and 4, spiking and MLP networks utilised their extended flight envelopes to quickly recover from being gusted; the highest angle used was for spiking networks in task 4 (34°), compared to the PID maximum of 20°. This behaviour was seen more frequently in the later tasks where stronger responses were required. Due to the amount of noise present and the variability of wind gusts, general controllers — unable to specialise to the conditions — were evolved.

Network Composition

Both neural networks benefit from the compressive effect of connection disabling; the best network of each type per task was always <50% connected. In the first task, MLP networks required significantly fewer connections and neurons than spiking networks (average 44.2% / 12.4 vs 48.3% / 14.8 respectively). The opposite is true in the final task (MLP av-

erage 50.9% / 15.2, spiking average 46.1% / 10.1). Smaller networks reduce computational requirements, increasing the chances that prospective onboard implementation will be viable. Plasticity increases with task difficulty, with significantly higher mean numbers of weight change events per network between tasks 1 and 3, 1 and 4, and 2 and 4, indicating that the extra flexibility permitted by the plasticity scheme is harnessed by the network.

Mutation Rates

Mutation rates generally increase throughout to allow sufficient exploration in more challenging tasks. Larger jumps are evidenced at the start of a new task (figure 3(b)) as the controllers require additional search of the network space to tailor the current population to the more complex task. After these peaks, small downward trends are evidenced as stability is brought into the search process. Peak size indicates how difficult the transition is for the controller.

Final rate values vary across tasks for the same controller. This highlights the context-sensitivity of the process and leads us to believe that a single mutation rate per parameter would be suboptimal overall. μ (rate of connection weight change), ω (rate of neuron addition/removal), and τ (rate of connection enabling/disabling) are often significantly higher in spiking networks than MLP networks — see table 2. A possible explanation is that the network types fundamentally differ in how they perform input-output mappings, and the spiking network space requires more variable search to locate fit solutions as a result.

Task	Controller	Best fit	Avg fit	G_{val}	$G_{0.5}$	$G_{1.0}$	$G_{1.5}$
	Spiking	50.3 (4.3)*	497.6 (127)	3.8 (3.9)†	9.3(5.2)†	6.7 (4.8)†	6.7 (4.8)†

4	τ	0.3 (0.09)	0.054 (0.01)

Table 2: Detailing averages and standard deviations for significantly different final self-adaptive mutation rates between the network types.

Effect of Incremental Evolution

In separate tests (not shown) we evolved spiking and MLP controllers for task 4 with random initial populations — neither produced a valid controller. This confirms that incremental evolution is seeding subsequent populations in useful areas of the search space. We also note that values of G_{val} for both networks generally decreases between experiments, i.e. valid controllers are evolved quickly despite the increasing difficulty of the task.

Discussion

We have demonstrated the benefits of spiking controllers for the control of dynamic platforms for dynamic tasks. The spiking controllers provided performance benefits on all tasks considered, with the fitness gap between spiking and MLP/PID control increasing with increasing task difficulty. Incremental evolution was found to be beneficial — seeded populations in harder tasks were significantly faster at creating valid controllers than random populations in the original, easiest task. Self-adaptive genetic search was found to

be beneficial in tailoring search rates to the task considered by allowing the various constituent parts of the network to vary at different rates, and by allowing increased network space exploration at the start of each new task to allow the controller to adapt to the environment.

Referring back to our hypothesis, we have shown that spiking networks were more able to cope with the unpredictabilities inherent in the tasks than the comparative controllers, possibly through harnessing latent temporal information in the wind which was effecting the quadrotor. Spiking controllers were significantly more rapid than MLPs in keeping the quadrotor within at least one of the predefined bounds $(G_{0.5}/G_{1.0}/G_{1.5})$ on all tasks considered.

Results encourage further experimentation — we aim to transfer our controllers to a physical quadrotor and expect that plasticity will play a more prominent role in providing online adaptation to discrepances between simulation and reality. We also wish to investigate the possibility of harnessing additional bio-inspired spiking mechanisms and integrating them into the neuro-controllers.

Evolving Multimodal Behavior Through Subtask and Switch Neural Networks

Abstract

While neuroevolution has been used successfully to discover effective control policies for intelligent agents, it has been difficult to evolve behavior that is multimodal, i.e. consists of distinctly different behaviors in different situations. This article proposes a new method, Modular NeuroEvolution of Augmenting Topologies (ModNEAT), to meet this challenge. ModNEAT decomposes complex tasks into tractable subtasks and utilizes neuroevolution to learn each subtask. Switch networks are evolved with the subtask networks to arbitrate among them and thus combine separate subtask networks into a complete hierarchical policy. Further, the need for new subtask modules is detected automatically by monitoring fitness of the agent population. Experimental results in the machine learning game of OpenNERO showed that ModNEAT outperforms the non-modular rtNEAT in both agent fitness and training efficiency.

Introduction

In complex real-world tasks, intelligent agents need to exhibit multimodal behavior. For instance, in robotic soccer keepaway, keeper agents try to complete as many passes to each other as possible while a taker does its best to steal the ball. When a keeper agent controls the ball, it needs to locate its teammates and pass the ball safely. When a teammate controls the ball, it needs to move to open position and prepare to receive passes (Whiteson, Kohl, Miikkulainen and Stone, 2005). Similarly, in an OpenNERO battle, two teams of agents fight to eliminate the enemy team with their weapons. Agents in each team must locate and navigate to enemy agents when they hide behind obstacles, and attack enemy agents when they fall into the weapon's range (Stanley, Bryant, Karpov and Miikkulainen, 2006).

To produce effective multimodal policies, complex tasks are often decomposed into tractable subtasks. Machine learning techniques can then be utilized to learn subtask behaviors. Subtask behaviors combined with an appropriate arbitration mechanism form a complete multimodal policy. The performance of such a policy depends on the division of the original task, the performance of subtask behaviors, and the mechanism for choosing among them. Therefore, an important research goal is to develop methods that decompose complex tasks automatically into tractable subtasks, learn effective behaviors in each subtask, and combine subtask behaviors to produce agents with effective multimodal behaviors.

A variety of methods exist for learning intelligent behaviors based on policy search; one of the most promising such methods is neuroevolution. Neuroevolution has been shown effective in discovering single control behaviors and has been widely applied to various control problems such as multilegged walking (Valsalam, Hiller, MacCurdy, Lipson and Miikkulainen, 2012; Clune, Beckmann, Ofria and Pennock, 2009), automated driving (Kohl, Stanley, Miikkulainen, Samples, and Sherony, 2006; Togelius, Lucas, and Nardi, 2007) and finless rocket control (Gomez and Miikkulainen, 2003). However, it is a challenging task to learn multimodal behaviors through neuroevolution.

One approach is to implement module mutation as part of the algorithm. This approach includes a structural mutation operator that adds a new module to a neural-network-based policy (Schrum and Miikkulainen, 2009). Several methods to implement module mutation have been proposed including Module Mutation Previous (MMP), Module Mutation Random (MMR), and Module Mutation Duplicate (MMD) (Schrum, 2014). Another approach is to use indirect encoding such as HyperNEAT to create the modules. Experimental results indicated that HyperNEAT is able to produce modular solutions rapidly for simple tasks that require multimodal behaviors (Clune, Beckmann, McKinley and Ofria, 2010). Various indirect encoding approaches can also be used to incorporate multimodality better in HyperNEAT (Pugh and Stanley, 2013). On the other hand, hierarchical learning approaches such as concurrent layered learning and coevolution were shown to work well in robotic keepaway soccer using neuroevolution with Enforced Sub-Populations (ESP). However, in the full robocup soccer simulator, homogeneous agents controlled by monolithic networks performed the best (Subramoney, 2012).

The prior studies concentrated on structural modification of neural-network-based policies, i.e. the initial structure and weights of new modules and how these modules could be best combined with existing modules. Thus, they did not address the problem of how such drastic modifications should be timed. Moreover, they did not demonstrate how proper arbitration between the subtasks could be discovered while evolving the subtask networks. This article proposes Modular NeuroEvolution of Augmenting Topologies (ModNEAT) as a solution to these problems. ModNEAT detects the need for module mutation by monitoring population fitness. Experimental results in the machine learning game of OpenNERO showed that ModNEAT is effective in finding appropriate task division and learning multimodal behaviors for complex tasks.

The remaining sections of this article are organized as follows: the next section introduces the ModNEAT algorithm, the third section presents and analyzes experimental results based on OpenNERO, and the fourth section reviews key ideas of this article and points out directions for future work. Following that is a brief conclusion.

Method

Modular NeuroEvolution with Augmenting Topologies (ModNEAT) is an evolutionary computation algorithm for learning multimodal policies with minimum human guidance. In this section, task decomposition and policy structure in ModNEAT are first introduced, followed by a description of the NEAT algorithm used for evolving the switch network and the subtask networks in a multimodal policy. The mechanism for adjusting the probability of module mutation based on population fitness is introduced next, and evolution of subtask and switch networks is discussed in the end.

Task Decomposition

To learn multimodal behaviors effectively, complex tasks are often decomposed into multiple subtasks (Jain, Subramoney and Miikkulainen, 2012). Machine learning techniques are applied to each subtask, and subtask policies combined to form a complete multimodal policy. In a neural-network-based multimodal policy, subtask policies are represented by different neural networks. Various mechanisms including human-specified rules, decision trees, and switch networks can be used to arbitrate among subtask policies (Whiteson, Kohl, Miikkulainen and Stone, 2005).

This approach is beneficial for two reasons. First, neural networks that are competent in one subtask may need to be adapted significantly to perform well in another subtask. By training neural networks separately for each subtask, selection in evolution becomes more focused, improving
